

STAT679

Computing for Data Science and Statistics

Lecture 11: `pandas`

Pandas

pandas

$$y_{it} = \beta' x_{it} + \mu_i + \epsilon_{it}$$

Open-source library of data analysis tools

Low-level ops implemented in Cython (C+Python=Cython, often faster)

Database-like structures, largely similar to those available in R

Well integrated with `numpy/scipy`

Optimized for most common operations

E.g., vectorized operations, operations on rows of a table

From the documentation: pandas is a Python package providing fast, flexible, and expressive data structures designed to make working with “relational” or “labeled” data both easy and intuitive. It aims to be the fundamental high-level building block for doing practical, real world data analysis in Python.

Installing pandas

pandas

$$y_{it} = \beta' x_{it} + \mu_i + \epsilon_{it}$$

Using conda:

```
conda install pandas
```

Using pip:

```
pip install pandas
```

From binary (not recommended):

<http://pypi.python.org/pypi/pandas>

Warning: a few recent updates to `pandas` have been API-breaking changes, meaning they changed one or more functions (e.g., changed the number of arguments, their default values, or other behaviors). This shouldn't be a problem for us, but you may as well check that you have the most recent version installed.

Basic Data Structures

Series: represents a one-dimensional **labeled** array

Labeled just means that there is an index into the array

Support vectorized operations

DataFrame: table of rows, with labeled columns

Like a spreadsheet or an R data frame

Support `numpy` ufuncs (provided data are numeric)

pandas Series

By default, indices are integers, starting from 0, just like you're used to.

```
1 import pandas as pd
2 import numpy as np
3 numbers = np.random.randn(5)
4 s = pd.Series(numbers)
5 s
```

```
0    -0.318743
1     0.807948
2    -0.216362
3    -0.356014
4     1.542122
dtype: float64
```

Can create a pandas Series from any array-like structure (e.g., Python list, numpy array, dict).

pandas tries to infer this data type automatically.

But we can specify a different set of indices if we so choose.

```
1 idx = ['a', 'b', 'c', 'd', 'e']
2 s = pd.Series(numbers, index=idx)
3 s
```

```
a    -0.318743
b     0.807948
c    -0.216362
d    -0.356014
e     1.542122
dtype: float64
```

Warning: providing too few or too many indices is a `ValueError`.

pandas Series

```
1 d = {'dog':3.1415,'cat':42,'bird':0,'goat':1.618}
2 s = pd.Series(d)
3 s
```

Can create a series from a dictionary. Keys become indices.

```
bird      0.0000
cat       42.0000
dog        3.1415
goat       1.6180
dtype: float64
```

```
1 inds = ['dog','cat','bird','goat','cthulu']
2 s = pd.Series(d, index=inds)
3 s
```

Index 'cthulu' doesn't appear in the dictionary, so pandas assigns it NaN, the standard "missing data" symbol.

```
dog        3.1415
cat        42.0000
bird        0.0000
goat        1.6180
cthulu      NaN
dtype: float64
```

pandas Series

Indexing works like you're used to and supports slices, but **not** negative indexing.

```
1 s = pd.Series([2,3,5,7,11])
2 s[0]
```

```
2
```

This object has type `np.int64`

```
1 s[1:3]
```

This object is another pandas Series.

```
1    3
2    5
dtype: int64
```

```
1 s[-1]
```

```
-----
KeyError                                Traceback (most recent call last)
<ipython-input-22-0e2107f91cbd> in <module>()
----> 1 s[-1]
```

pandas Series

```
1 s = pd.Series([2,3,5,7,11], index=['a','a','a','a','a'])
2 s
```

```
a    2
a    3
a    5
a    7
a   11
dtype: int64
```

Caution: indices need not be unique in pandas Series. This will only cause an error if/when you try to perform an operation that requires unique indices.

```
1 s['a']
```

```
a    2
a    3
a    5
a    7
a   11
dtype: int64
```

pandas Series

```
1 s
dog      3.1415
cat      42.0000
bird      0.0000
goat      1.6180
cthulu    NaN
dtype: float64
```

Series objects are like `np.ndarray` objects, so they support all the same kinds of slice operations, but note that the indices come along with the slices.

```
1 s[s>0]
dog      3.1415
cat      42.0000
goat      1.6180
dtype: float64
```

Series objects even support most `numpy` functions that act on arrays.

```
1 s**2
dog      9.869022
cat     1764.000000
bird      0.000000
goat      2.617924
cthulu    NaN
dtype: float64
```

pandas Series

```
1 s
dog      3.1415
cat      42.0000
bird     0.0000
goat     1.6180
cthulu   NaN
dtype: float64
```

Series objects are dict-like, in that we can access and update entries via their keys.

```
1 s['goat']
1.6180000000000001
```

```
1 s['cthulu']=-1
2 s
```

```
dog      3.1415
cat      42.0000
bird     0.0000
goat     1.6180
cthulu   -1.0000
dtype: float64
```

Not shown: Series also support the `in` operator: `x in s` checks if `x` appears as an index of Series `s`. Series also supports the dictionary `get` method.

Like a dictionary, accessing a non-existent key is a `KeyError`.

```
1 s['penguin']
```

```
-----
KeyError
<ipython-input-48-a7df9b66ea8a>
----> 1 s['penguin']
```

Note: I cropped out a bunch of the error message, but you get the idea.

pandas Series

```
1  s
dog      3.1415
cat      42.0000
bird     0.0000
goat     1.6180
cthulu   -1.0000
dtype: float64
```

Entries of a Series can be of (almost) any type, and they may be mixed (e.g., some floats, some ints, some strings, etc), but they **can not** be sequences.

```
1  s['cthulu'] = (1,1)
```

ValueError

<ipython-input-50-47579d9278ca>

----> 1 s['cthulu'] = (1,1)

```
/Users/keith/anaconda/lib/python2.7/site-packages/pandas
```

```
744         # GH 6043
```

```
745         elif _is_scalar_indexer(indexer):
```

```
--> 746             values[indexer] = value
```

```
747
```

```
748         # if we are an exact match (ex-broad
```

ValueError: setting an array element with a sequence.

More information on indexing:

<https://pandas.pydata.org/pandas-docs/stable/indexing.html>

pandas Series

```
1 s
dog      3.1415
cat      42
bird     0
goat     1.618
cthulu   abcde
dtype: object
```

Series support universal functions, so long as all their entries support operations.

```
1 s + 2*s
dog      9.4245
cat      126
bird     0
goat     4.854
cthulu   abcdeabcdeabcde
dtype: object
```

Series operations require that keys be shared. Missing values become NaN by default.

```
1 d = {'dog':2, 'cat':1.23456}
2 t = pd.Series(d)
3 t
cat      1.23456
dog      2.00000
dtype: float64
```

```
1 s+t
bird     NaN
cat      43.2346
cthulu   NaN
dog      5.1415
goat     NaN
dtype: object
```

To reiterate, Series objects support most `numpy` ufuncs. For example, `np.sqrt(s)` is valid, so long as all entries are positive.

pandas Series

```
1 s
bird    0.0000
cat     42.0000
dog     3.1415
goat    1.6180
dtype: float64
```

Series have an optional name attribute.

```
1 s.name = 'aminals'
2 s
bird    0.0000
cat     42.0000
dog     3.1415
goat    1.6180
Name: aminals, dtype: float64
```

After it is set, name attribute can be changed with `rename` method.

```
1 s.rename('animals')
bird    0.0000
cat     42.0000
dog     3.1415
goat    1.6180
Name: animals, dtype: float64
```

Note: this returns a new Series. It **does not** change `s.name`.

This will become especially useful when we start talking about DataFrames, because these name attributes will be column names.

Mapping and linking Series values

```
1 s = pd.Series(['dog', 'goat', 'skunk'])
2 s
0      dog
1     goat
2    skunk
dtype: object
```

Series `map` method works analogously to Python's `map` function. Takes a function and applies it to every entry.

```
3 s.map(lambda s: len(s))
0      3
1      4
2      5
dtype: int64
```

Mapping and linking Series values

```
1 s = pd.Series(['fruit', 'animal', 'animal', 'fruit', 'fruit'],
2               index=['apple', 'cat', 'goat', 'banana', 'kiwi'])
3 s
```

```
apple    fruit
cat      animal
goat     animal
banana   fruit
kiwi     fruit
dtype: object
```

```
1 t = pd.Series({'fruit':0, 'animal':1})
2 s.map(t)
```

```
apple    0
cat      1
goat     1
banana   0
kiwi     0
dtype: int64
```

Series `map` also allows us to change values based on another Series. Here, we're changing the fruit/animal category labels to binary labels.

pandas DataFrames

Fundamental unit of pandas

Analogous to R data frame

2-dimensional structure (i.e., rows and columns)

Columns, of potentially different types

Think: spreadsheet (or, better, database, but we haven't learned those, yet)

Can be created from many different objects

Dict of {ndarrays, Python lists, dicts, Series}

2-dimensional ndarray

Series

pandas DataFrames

Creating a DataFrame from a dictionary, the keys become the column names. Values become the columns of the dictionary.

```
1 d = {'A':pd.Series([1,2,3], index=['cat','dog','bird']),  
2     'B':{'cat':3.14, 'dog':2.718, 'bird':1.618, 'goat':0.5772}}  
3 df = pd.DataFrame(d)  
4 df
```

	A	B
bird	3.0	1.6180
cat	1.0	3.1400
dog	2.0	2.7180
goat	NaN	0.5772

Each column may have its own indices, but the resulting DataFrame will have a row for every index (i.e., every row name) that appears.

Indices that are unspecified for a given column receive NaN.

Note: in the code above, we specified the two columns differently. One was specified as a Series object, and the other as a dictionary. This is just to make the point that there is flexibility in how you construct your DataFrame. More options:

<https://pandas.pydata.org/pandas-docs/stable/generated/pandas.DataFrame.html>

pandas DataFrames: creating DataFrames

Dictionary has 4 keys, so 4 columns.

```
1 d = {'Undergrad' : pd.Series(['UMich', 'Stanford', 'Princeton', 'Columbia'],
2                               index=['Ford', 'Hoover', 'Wilson', 'Obama']),
3      'PhD' : {'Wilson':'Johns Hopkins'},
4      'JD' : {'Ford':'Yale', 'Obama':'Harvard'},
5      'Terms' : pd.Series([1,1,2,2], index=['Ford', 'Hoover', 'Wilson', 'Obama']) }
6 presidents = pd.DataFrame(d)
7 presidents
```

Note: Dictionary includes both text and numeric columns

	JD	PhD	Terms	Undergrad
Ford	Yale	NaN	1	UMich
Hoover	NaN	NaN	1	Stanford
Obama	Harvard	NaN	2	Columbia
Wilson	NaN	Johns Hopkins	2	Princeton

By default, rows and columns are ordered alphabetically.

pandas DataFrames: row/column names

	JD	PhD	Terms	Undergrad
Ford	Yale	NaN	1	UMich
Hoover	NaN	NaN	1	Stanford
Obama	Harvard	NaN	2	Columbia
Wilson	NaN	Johns Hopkins	2	Princeton

Row and column names accessible as the `index` and `columns` attributes, respectively, of the DataFrame.

```
1 presidents.columns
```

```
Index([u'JD', u'PhD', u'Terms', u'Undergrad'], dtype='object')
```

```
1 presidents.index
```

```
Index([u'Ford', u'Hoover', u'Obama', u'Wilson'], dtype='object')
```

Both are returned as pandas Index objects.

pandas DataFrames: accessing/adding columns

```
1 presidents['PhD']  
Ford          NaN  
Hoover        NaN  
Obama         NaN  
Wilson      Johns Hopkins  
Name: PhD, dtype: object
```

DataFrame acts like a dictionary whose keys are column names, values are Series.

```
1 type(presidents['PhD'])  
pandas.core.series.Series
```

```
1 presidents['Years'] = 4*presidents['Terms']  
2 presidents
```

Like a dictionary, we can create new key-value pairs.

	JD	PhD	Terms	Undergrad	Years
Ford	Yale	NaN	1	UMich	4
Hoover	NaN	NaN	1	Stanford	4
Obama	Harvard	NaN	2	Columbia	8
Wilson	NaN	Johns Hopkins	2	Princeton	8

Note: technically, this isn't quite correct, because Ford did not serve a full term.
https://en.wikipedia.org/wiki/Gerald_Ford

pandas DataFrames: accessing/adding columns

	JD	PhD	Terms	Undergrad	Years
Ford	Yale	NaN	1	UMich	4
Hoover	NaN	NaN	1	Stanford	4
Obama	Harvard	NaN	2	Columbia	8
Wilson	NaN	Johns Hopkins	2	Princeton	8

```
1 presidents['Nobels'] = [0,0,1,1]
2 presidents
```

Since the row labels are ordered, we can specify a new column directly from a Python list, `numpy` array, etc. without having to specify indices.

	JD	PhD	Terms	Undergrad	Years	Nobels
Ford	Yale	NaN	1	UMich	4	0
Hoover	NaN	NaN	1	Stanford	4	0
Obama	Harvard	NaN	2	Columbia	8	1
Wilson	NaN	Johns Hopkins	2	Princeton	8	1

Note: by default, new columns are inserted at the end. See the `insert` method to change this behavior: <https://pandas.pydata.org/pandas-docs/stable/generated/pandas.DataFrame.insert.html>

pandas DataFrames: accessing/adding columns

	JD	PhD	Terms	Undergrad	Nobels	Years
Ford	Yale	NaN	1	UMich	0	4
Hoover	NaN	NaN	1	Stanford	0	4
Obama	Harvard	NaN	2	Columbia	1	8
Wilson	NaN	Johns Hopkins	2	Princeton	1	8

```
1 presidents['Fields Medals'] = 0  
2 presidents
```

Scalars are broadcast across the rows.

	JD	PhD	Terms	Undergrad	Nobels	Years	Fields Medals
Ford	Yale	NaN	1	UMich	0	4	0
Hoover	NaN	NaN	1	Stanford	0	4	0
Obama	Harvard	NaN	2	Columbia	1	8	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	8	0

Deleting columns

	JD	PhD	Terms	Undergrad	Nobels	Years	Fields Medals
Ford	Yale	NaN	1	UMich	0	4	0
Hoover	NaN	NaN	1	Stanford	0	4	0
Obama	Harvard	NaN	2	Columbia	1	8	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	8	0

```
1 del presidents['Years']  
2 presidents
```

Delete columns identically to deleting keys from a dictionary. One can use the `del` keyword, or `pop` a key.

	JD	PhD	Terms	Undergrad	Nobels	Fields Medals
Ford	Yale	NaN	1	UMich	0	0
Hoover	NaN	NaN	1	Stanford	0	0
Obama	Harvard	NaN	2	Columbia	1	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	0

```
1 fields = presidents.pop('Fields Medals')
```

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1
	Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents.loc['Obama']
```

```
JD          Harvard
PhD         NaN
Terms       2
Undergrad   Columbia
Nobels      1
Name: Obama, dtype: object
```

`df.loc` selects rows by their labels.
`df.iloc` selects rows by their integer labels (starting from 0).

```
1 presidents.iloc[1]
```

```
JD          NaN
PhD         NaN
Terms       1
Undergrad   Stanford
Nobels      0
Name: Hoover, dtype: object
```

```
1 presidents['JD']
```

```
Ford      Yale
Hoover    NaN
Obama     Harvard
Wilson    NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
```

	Terms	Undergrad	Nobels
	1	Stanford	0
	2	Columbia	1

```
1 presidents[presidents['Terms'] < 2]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1
	Wilson	NaN	Johns Hopkins	2	Princeton	1

Select columns by their names.

```
1 presidents
JD          Harvard
PhD         NaN
Terms       2
Undergrad   Columbia
Nobels      1
Name: Obama, dtype: object
```

```
1 presidents.iloc[1]
```

```
JD          NaN
PhD         NaN
Terms       1
Undergrad   Stanford
Nobels      0
Name: Hoover, dtype: object
```

```
1 presidents['JD']
```

```
Ford      Yale
Hoover    NaN
Obama     Harvard
Wilson    NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1

```
1 presidents[presidents['Terms']<2]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1
	Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents
JD
PhD
Terms
Undergrad  Columbia
Nobels
Name: Obama, dtype: object
```

Select rows by their numerical indices (again 0-indexed). This supports slices.

Note: one can also select slices with lists of column names, e.g., `presidents[['JD', 'PhD']]`.

```
1 presidents
JD          NaN
PhD         NaN
Terms       1
Undergrad   Stanford
Nobels      0
Name: Hoover, dtype: object
```

```
1 presidents['JD']
Ford      Yale
Hoover    NaN
Obama     Harvard
Wilson    NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
JD  PhD  Terms  Undergrad  Nobels
Hoover  NaN  NaN    1    Stanford    0
Obama  Harvard  NaN    2    Columbia    1
```

```
1 presidents[presidents['Terms'] < 2]
JD  PhD  Terms  Undergrad  Nobels
Ford  Yale  NaN    1    UMich    0
Hoover  NaN  NaN    1    Stanford    0
```

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1
	Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents.loc['Obama']
```

```
JD          Harvard
PhD         NaN
Terms       2
Undergrad   Columbia
Nobels      1
Name: Obama, dtype: object
```

```
1 presidents.iloc[1]
```

```
JD          NaN
PhD         NaN
Terms       1
Undergrad   Stanford
Nobels      0
Name: Hoover, dtype: object
```

Select rows by Boolean expression.

```
1 presidents['JD']
```

```
Ford      Yale
Hoover    NaN
Obama     Harvard
Wilson    NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1

```
1 presidents[presidents['Terms'] < 2]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1
	Wilson	NaN	Johns Hopkins	2	Princeton	1

```
presidents.loc['Obama']
```

```
JD          Harvard
PhD         NaN
Terms       2
Undergrad   Columbia
Nobels      1
Name: Obama, dtype: object
```

```
presidents.iloc[1]
```

```
JD          NaN
PhD         NaN
Terms       1
Undergrad   Stanford
Nobels      0
Name: Hoover, dtype: object
```

These expressions return Series objects.

```
presidents['JD']
```

```
Ford      Yale
Hoover    NaN
Obama     Harvard
Wilson    NaN
Name: JD, dtype: object
```

```
presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Hoover	NaN	NaN	1	Stanford	0
	Obama	Harvard	NaN	2	Columbia	1

```
presidents[presidents['Terms'] < 2]
```

	JD	PhD	Terms	Undergrad	Nobels	
	Ford	Yale	NaN	1	UMich	0
	Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1
Wilson	NaN	Johns Hopkins	2	Princeton	1

```
presidents['JD']
```

	JD	PhD
Ford	Yale	NaN
Hoover	NaN	NaN
Obama	Harvard	NaN
Wilson	NaN	NaN

Name: JD, dtype: object

```
presidents.loc['Obama']
```

	JD	PhD	Terms	Undergrad	Nobels
Obama	Harvard	NaN	2	Columbia	1

Name: Obama, dtype: object

These expressions return Series objects.

```
presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1

These expressions return DataFrames.

```
presidents.iloc[1]
```

	JD	PhD	Terms	Undergrad	Nobels
Hoover	NaN	NaN	1	Stanford	0

Name: Hoover, dtype: object

```
presidents[presidents['Terms'] < 2]
```

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0

More on indexing:
<https://pandas.pydata.org/pandas-docs/stable/indexing.html>

Arithmetic with DataFrames

```
1 df1 = pd.DataFrame(np.random.randn(8, 4), columns=['A', 'B', 'C', 'D'])
2 df2 = pd.DataFrame(np.random.randn(5, 3), columns=['A', 'B', 'C'])
3 df1+df2
```

	A	B	C	D
0	0.722814	-1.889204	-1.170304	NaN
1	1.370720	-1.033425	-0.719628	NaN
2	-2.281526	0.899515	-0.298246	NaN
3	-4.276271	-2.327304	-0.444528	NaN
4	-1.418512	0.463528	0.428446	NaN
5	NaN	NaN	NaN	NaN
6	NaN	NaN	NaN	NaN
7	NaN	NaN	NaN	NaN

pandas tries to align the DataFrames as best it can, filling in non-alignable entries with NaN.

In this example, rows 0 through 4 and columns A through C exist in both DataFrames, so these entries can be successfully added. All other entries get NaN, because $x + \text{NaN} = \text{NaN}$.

Arithmetic with DataFrames

```
1 df = pd.DataFrame(np.random.randn(4, 2), columns=['A', 'B'])
2 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

By default, Series are aligned to DataFrames via row-wise broadcasting.

```
1 df - df.iloc[0]
```

	A	B
0	0.000000	0.000000
1	2.442791	0.794009
2	0.661785	0.957734
3	1.548277	-0.136072

`df.iloc[0]` is a Series representing the 0-th row of `df`. When we try to subtract it from `df`, pandas forces dimensions to agree by broadcasting the operation across all rows of `df`.

Arithmetic with DataFrames

```
1 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

```
1 10*df + 1
```

	A	B
0	-12.316346	-4.008702
1	12.111569	3.931385
2	-5.698497	5.568633
3	3.166428	-5.369423

Scalar addition and multiplication works in the obvious way. DataFrames also support scalar division, exponentiation... Basically every `numpy` ufunc.

DataFrames also support entrywise Boolean operations.

```
1 df > 0
```

	A	B
0	False	False
1	True	True
2	False	True
3	True	False

Arithmetic with DataFrames

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

pandas DataFrames support
numpy-like any and all methods.

```
1 (df > 0).any()
```

```
A    True  
B    True  
dtype: bool
```

```
1 (df > 0).all()
```

```
A    False  
B    False  
dtype: bool
```

Just like `numpy`, direct
Boolean operations are
not supported.

```
1 df or df
```

```
-----  
ValueError
```

```
ValueError: The truth value of a  
DataFrame is ambiguous.  
Use a.empty, a.bool(), a.item(),  
a.any() or a.all().
```

Arithmetic with DataFrames

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

`values` attribute stores the entries of the table in a numpy array. This is occasionally useful when you want to stop dragging the extra information around and just work with the numbers in the table.

```
1 df.values
```

```
array([[ -1.33163456,  -0.50087024],  
       [  1.11115689,   0.29313846],  
       [-0.66984966,   0.45686335],  
       [  0.21664278,  -0.63694229]])
```

Arithmetic with DataFrames

```
1 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

DataFrames support entrywise multiplication. The `T` attribute is the transpose of the DataFrame.

```
df.T*df.T
```

	0	1	2	3
A	1.773251	1.23467	0.448699	0.046934
B	0.250871	0.08593	0.208724	0.405695

DataFrames also support matrix multiplication via the `numpy`-like `dot` method. The DataFrame dimensions must be conformal, of course.

```
df.T.dot(df)
```

	A	B
A	3.503553	0.548680
B	0.548680	0.951221

Note: Series also support a `dot` method, so you can compute inner products.

Removing NaNs

	A	B	C	D
0	-9.422331	1.100197	8.034010	NaN
1	-1.520140	5.655382	-1.692761	NaN
2	0.399654	10.058568	0.502007	NaN
3	-4.070947	2.237868	10.530079	NaN
4	1.603739	8.255591	1.892258	NaN
5	1.123450	3.141590	NaN	NaN

DataFrame `dropna` method removes rows or columns that contain NaNs.

`axis` argument controls whether we act on rows, columns, etc.

`how='any'` will remove all rows/columns that contain even one NaN. `how='all'` removes rows/columns that have all entries NaN.

```
1 df.dropna(axis=1, how='any')
```

	A	B
0	-9.422331	1.100197
1	-1.520140	5.655382
2	0.399654	10.058568
3	-4.070947	2.237868
4	1.603739	8.255591
5	1.123450	3.141590

```
1 df.dropna(axis=1, how='all')
```

	A	B	C
0	-9.422331	1.100197	8.034010
1	-1.520140	5.655382	-1.692761
2	0.399654	10.058568	0.502007
3	-4.070947	2.237868	10.530079
4	1.603739	8.255591	1.892258
5	1.123450	3.141590	NaN

Reading/writing files

`pandas` supports read/write for a wide range of different file formats. This flexibility is a major advantage of `pandas`.

Format Type	Data Description	Reader	Writer
text	CSV	<code>read_csv</code>	<code>to_csv</code>
text	JSON	<code>read_json</code>	<code>to_json</code>
text	HTML	<code>read_html</code>	<code>to_html</code>
text	Local clipboard	<code>read_clipboard</code>	<code>to_clipboard</code>
binary	MS Excel	<code>read_excel</code>	<code>to_excel</code>
binary	HDF5 Format	<code>read_hdf</code>	<code>to_hdf</code>
binary	Feather Format	<code>read_feather</code>	<code>to_feather</code>
binary	Parquet Format	<code>read_parquet</code>	<code>to_parquet</code>
binary	Msgpack	<code>read_msgpack</code>	<code>to_msgpack</code>
binary	Stata	<code>read_stata</code>	<code>to_stata</code>
binary	SAS	<code>read_sas</code>	
binary	Python Pickle Format	<code>read_pickle</code>	<code>to_pickle</code>
SQL	SQL	<code>read_sql</code>	<code>to_sql</code>
SQL	Google Big Query	<code>read_gbq</code>	<code>to_gbq</code>

Reading/writing files

`pandas` supports read/write for a wide range of different file formats. This flexibility is a major advantage of `pandas`.

Format Type	Data Description	Reader	Writer
text	CSV	<code>read_csv</code>	<code>to_csv</code>
text	JSON	<code>read_json</code>	<code>to_json</code>
text	HTML	<code>read_html</code>	<code>to_html</code>
text	Local clipboard	<code>read_clipboard</code>	<code>to_clipboard</code>
binary	MS Excel	<code>read_excel</code>	<code>to_excel</code>
		<code>read_hdf</code>	<code>to_hdf</code>
		<code>read_feather</code>	<code>to_feather</code>
		<code>read_parquet</code>	<code>to_parquet</code>
binary	Msgpack	<code>read_msgpack</code>	<code>to_msgpack</code>
binary	Stata	<code>read_stata</code>	<code>to_stata</code>

binary	Python Pickle Format	<code>read_pickle</code>	<code>to_pickle</code>
SQL	SQL	<code>read_sql</code>	<code>to_sql</code>
SQL	Google Big Query	<code>read_gbq</code>	<code>to_gbq</code>

`pandas` file I/O is largely similar to R `read.table` and similar functions, so I'll leave it to you to read the `pandas` documentation as needed.

Summarizing DataFrames

`pd.read_csv()` reads a comma-separated file into a DataFrame.

`info()` method prints summary data about the DataFrame. Number of rows, column names and their types, etc.

Note: there is a separate `to_string()` method that generates a string representing the DataFrame in tabular form, but this usually doesn't display well if you have many columns.

```
1 baseball = pd.read_csv('baseball.csv')
2 baseball.info()

<class 'pandas.core.frame.DataFrame'>
Int64Index: 21699 entries, 4 to 89534
Data columns (total 22 columns):
id          21699 non-null object
year       21699 non-null int64
stint      21699 non-null int64
team       21699 non-null object
lg         21634 non-null object
g          21699 non-null int64
ab         21699 non-null int64
r          21699 non-null int64
h          21699 non-null int64
X2b        21699 non-null int64
X3b        21699 non-null int64
hr         21699 non-null int64
rbi        21687 non-null float64
sb         21449 non-null float64
cs         17174 non-null float64
bb         21699 non-null int64
so         20394 non-null float64
ibb        14171 non-null float64
hbp        21322 non-null float64
sh         20739 non-null float64
sf         14309 non-null float64
gidp       16427 non-null float64
dtypes: float64(9), int64(10), object(3)
memory usage: 3.8+ MB
```

Summarizing DataFrames

`head()` method displays just the first few rows of the DataFrame (5 by default; change this by supplying an argument). `tail()` displays the last few rows.

```
1 baseball.head()
```

	id	year	stint	team	lg	g	ab	r	h	X2b	...	rbi	sb	cs	bb	so	ibb	hbp	sh	sf	gidp
4	ansonca01	1871	1	RC1	NaN	25	120	29	39	11	...	16.0	6.0	2.0	2	1.0	NaN	NaN	NaN	NaN	NaN
44	forceda01	1871	1	WS3	NaN	32	162	45	45	9	...	29.0	8.0	0.0	4	0.0	NaN	NaN	NaN	NaN	NaN

102	suttoez01	1871	1	CL1	NaN	29	128	35	45	3	...	23.0	3.0	1.0	1	0.0	NaN	NaN	NaN	NaN	NaN

5 rows x 22 columns

Note: R and pandas both supply `head/tail` functions, named after UNIX/Linux commands that displays the first/last lines of a file.

Comparing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

These two DataFrames
ought to be equivalent...

...but they aren't.

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

```
A    False
B    False
C    False
D    False
dtype: bool
```

```
1 np.nan == np.nan
```

```
False
```

```
1 df1.equals(df2)
```

```
True
```

Comparing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

These two DataFrames
ought to be equivalent...

...but they aren't.

The problem comes from the fact that
NaNs are not equal to one another.

Solution: DataFrames have a separate
`equals()` method for checking the kind
of equality that we meant above.

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

```
A    False
B    False
C    False
D    False
dtype: bool
```

```
1 np.nan == np.nan
```

```
False
```

```
1 df1.equals(df2)
```

```
True
```

Comparing DataFrames

There is a solid design principle behind this. If there are NaNs in our data, we want to err on the side of being overly careful about what operations we perform on them. We see similar ideas in `numpy` and in R.

Solution: DataFrames have a separate `equals()` method for checking the kind of equality that we meant above.

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

```
A    False
B    False
C    False
D    False
dtype: bool
```

```
1 np.nan == np.nan
```

```
False
```

```
1 df1.equals(df2)
```

```
True
```

Statistical Operations on DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

Getting means of DataFrame rows/columns using numpy is possible, but tedious.

```
1 np.nanmean(np.array(df.iloc[1]))
```

```
-0.50977640954057268
```

`DataFrame.mean` method is a cleaner way to do the same thing. Argument picks out which axis to take means on: rows (1) or columns (0).

```
1 df.mean(0)
A    -4.706220
B    -3.109512
C    -1.763407
D         NaN
dtype: float64
```

```
1 df.mean(1)
0    -3.115592
1    -0.509776
2    -2.240343
3    -9.397471
4    -0.702050
5         NaN
dtype: float64
```

Statistical Operations on DataFrames

	A	B	C	D
0	2.0	1.0	3.0	4.0
1	5.0	2.0	4.0	5.0
2	-9.0	3.0	5.0	6.0
3	-17.0	4.0	6.0	7.0
4	-5.0	5.0	7.0	8.0
5	1.0	6.0	8.0	9.0

Of course, DataFrames also support a bunch of related functions, that work similarly: `sum`, `min`, `max`, `std`, `var` etc. All of these functions take an optional Boolean argument `skipna`. If `True`, NaNs are **not included** in the computation. If `False`, NaNs are included (which can mean either that the computation doesn't work at all, or changes the value only slightly). More information: <https://pandas.pydata.org/pandas-docs/stable/basics.html#descriptive-statistics>

```
1 np.nanmean(np.array(df.iloc[1]))
-0.50977640954057268
```

`DataFrame.mean` method is a cleaner way to do the same thing. Argument picks out which axis to take means on: rows (1) or columns (0).

```
1 df.mean(0)
A    -4.706220
B    -3.109512
C    -1.763407
D             NaN
dtype: float64
```

```
1 df.mean(1)
0    -3.115592
1    -0.509776
2    -2.240343
3    -9.397471
4    -0.702050
5             NaN
dtype: float64
```

Summarizing DataFrames

`DataFrame.describe()` is similar to the R `summary()` function. Non-numeric data will get statistics like counts, number of unique items, etc. If a DataFrame has mixed types (both numeric and non-numeric), the non-numeric data is excluded by default.

Details and optional arguments:

<https://pandas.pydata.org/pandas-docs/stable/basics.html#summarizing-data-describe>

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

`df.describe()`

	A	B	C	D
count	5.000000	5.000000	5.000000	0.0
mean	-4.706220	-3.109512	-1.763407	NaN
std	9.161650	5.676551	2.354438	NaN
min	-17.105085	-9.309218	-4.681215	NaN
25%	-9.126106	-7.556816	-2.878510	NaN
50%	-5.674048	-4.133700	-1.778110	NaN
75%	2.891255	1.854114	-1.192984	NaN
max	5.482881	3.598060	1.713784	NaN

Row- and column-wise functions: `apply()`

	A	B	C	D
0	1.284355	1.073402	0.297575	NaN
1	-0.791592	0.841969	0.509262	NaN
2	-0.657900	-2.184139	1.635736	NaN
3	-1.897574	0.502787	-1.911790	NaN
4	0.592821	2.091333	-2.813032	NaN
5	NaN	NaN	NaN	NaN

`DataFrame.apply()` takes a function and applies it to each column of the DataFrame.

```
df.apply(np.mean)
```

```
A    -0.293978  
B     0.465070  
C    -0.456450  
D         NaN  
dtype: float64
```

`axis` argument is 0 by default (column-wise). Change to 1 for row-wise application.

```
df.apply(np.mean, axis=1)
```

```
0     0.885111  
1     0.186546  
2    -0.402101  
3    -1.102192  
4    -0.042959  
5         NaN  
dtype: float64
```

Row- and column-wise functions: `apply()`

	A	B	C	D
0	1.284355	1.073402	0.297575	NaN
1	-0.791592	0.841969	0.509262	NaN
2	-0.657900	-2.184139	1.635736	NaN
3	-1.897574	0.502787	-1.911790	NaN
4	0.592821	2.091333	-2.813032	NaN
5	NaN	NaN	NaN	NaN

Numpy ufuncs take vectors and spit out vectors, so using `df.apply()` to apply a ufunc to every row or column in effect ends up applying the ufunc to every element.

```
df.apply(np.exp)
```

	A	B	C	D
0	3.612337	2.925314	1.346589	NaN
1	0.453123	2.320931	1.664062	NaN
2	0.517938	0.112575	5.133236	NaN
3	0.149932	1.653323	0.147816	NaN
4	1.809085	8.095701	0.060023	NaN
5	NaN	NaN	NaN	NaN

	A	B	C
0	0.938898	2.047553	-0.525091
1	1.066293	-0.599466	-0.195606
2	-0.939341	0.022376	1.453082
3	1.114664	-0.408026	-0.811081
4	2.257680	0.280994	0.847329

Row- and column-wise functions: `apply()`

```
1 def quadratic(x, a, b, c=1):  
2     return a*x**2 + b*x + c  
3 df.apply(quadratic, args=(1,2), c=5)
```

We can pass positional and keyword arguments into the function via `df.apply`. `Args` is a tuple of the positional arguments (in order), followed by the keyword arguments.

	A	B	C
0	7.759325	13.287581	4.225538
1	8.269566	4.160428	4.647050
2	4.003679	5.045253	10.017612
3	8.471805	4.350433	4.035691
4	14.612481	5.640946	7.412624

Note: “`apply()` takes an argument `raw` which is `False` by default, which converts each row or column into a `Series` before applying the function. When set to `True`, the passed function will instead receive an `ndarray` object, which has positive performance implications if you do not need the indexing functionality.” This can be useful if your function is meant to work specifically with `Series`.

Element-wise function application

```
1 df = pd.DataFrame({'A': ['cat', 'dog', 'bird'],  
2                    'B': ['unicorn', 'chupacabra', 'pixie']})  
3 df
```

	A	B
0	cat	unicorn
1	dog	chupacabra
2	bird	pixie

This causes an error, because `apply` thinks that its argument should be applied to Series (i.e., columns), not to individual entries.

```
1 df.apply(lambda s:s.upper())
```

```
-----  
AttributeError                                Traceback (most recent  
<ipython-input-507-61f17bcd25de> in <module>()  
----> 1 df.apply(lambda s:s.upper())
```

Element-wise function application

`applymap` works similarly to Python's `map` function (and the `Series` `map` method). Applies its argument function to every entry of the DataFrame.

	A	B
0	cat	unicorn
1	dog	chupacabra
2	bird	pixie

```
df.applymap(lambda s:s.upper())
```

	A	B
0	CAT	UNICORN
1	DOG	CHUPACABRA
2	BIRD	PIXIE

Tablewise Function Application

Here we have a function composition applied to a DataFrame. This is perfectly valid code, but pandas supports another approach.

```
1 f = lambda x:x**2
2 g = lambda x:x+1
3 h = lambda x:2*x
4 df = pd.DataFrame(np.random.randn(5, 3),
5                   columns=['A', 'B', 'C'])
6 df
```

	A	B	C
0	-2.072339	-1.282539	-1.241128
1	-0.587874	0.517591	-0.394561
2	-0.164436	1.450398	-0.975424
3	-1.215576	-0.671235	0.394053
4	-0.350299	1.958805	0.467778

```
1 h(g(f(df)))
```

	A	B	C
0	10.589182	5.289812	5.080798
1	2.691193	2.535802	2.311357
2	2.054078	6.207308	3.902906
3	4.955251	2.901113	2.310556
4	2.245419	9.673833	2.437633

Tablewise Function Application

The DataFrame `pipe` method is built for a pattern called **method chaining**. The `pipe` method has better support for passing additional arguments around than does the function composition to the right. This pattern using `pipe` is also more conducive to functional programming patterns.

```
1 df.pipe(f).pipe(g).pipe(h)
```

	A	B	C
0	10.589182	5.289812	5.080798
1	2.691193	2.535802	2.311357
2	2.054078	6.207308	3.902906
3	4.955251	2.901113	2.310556
4	2.245419	9.673833	2.437633

```
1 f = lambda x:x**2
2 g = lambda x:x+1
3 h = lambda x:2*x
4 df = pd.DataFrame(np.random.randn(5, 3),
5                   columns=['A', 'B', 'C'])
6 df
```

	A	B	C
0	-2.072339	-1.282539	-1.241128
1	-0.587874	0.517591	-0.394561
2	-0.164436	1.450398	-0.975424
3	-1.215576	-0.671235	0.394053
4	-0.350299	1.958805	0.467778

```
1 h(g(f(df)))
```

	A	B	C
0	10.589182	5.289812	5.080798
1	2.691193	2.535802	2.311357
2	2.054078	6.207308	3.902906
3	4.955251	2.901113	2.310556
4	2.245419	9.673833	2.437633

Recap

Previously: basics of pandas

- Series and DataFrames

- Indexing, changing entries

- Function application

Next: more complicated operations

- Statistical computations

- Group-By operations

- Reshaping, stacking and pivoting

pandas

$$y_{it} = \beta' x_{it} + \mu_i + \epsilon_{it}$$

Recap

Previously: basics of `pandas`

- Series and DataFrames

- Indexing, changing entries

- Function application

Next: more complicated operations

- Statistical computations

- Group-By operations

- Reshaping, stacking and pivoting

pandas

$$y_{it} = \beta' x_{it} + \mu_i + \epsilon_{it}$$

Caveat: `pandas` is a large, complicated package, so I will not endeavor to mention every feature here. These slides should be enough to get you started, but there's no substitute for reading the documentation.

Percent change over time

`pct_change` method is supported by both Series and DataFrames. `Series.pct_change` returns a new Series representing the step-wise percent change.

Note: `pandas` has extensive support for time series data, which we mostly won't talk about in this course. Refer to the documentation for more.

```
1 s = pd.Series(np.random.randn(8))
2 s

0    -0.669520
1    -0.864352
2    -1.686718
3     0.014609
4    -2.199920
5    -0.505137
6    -0.403893
7    -0.358685
dtype: float64
```

```
1 s.pct_change()

0         NaN
1     0.291003
2     0.951425
3    -1.008661
4   -151.589298
5    -0.770384
6    -0.200428
7    -0.111931
dtype: float64
```

Percent change over time

`pct_change` operates on columns of a DataFrame, by default. `Periods` argument specifies the time-lag to use in computing percent change. So `periods=2` looks at percent change compared to two time steps ago.

	0	1	2	3
0	-0.305249	-0.364416	0.815636	0.189141
1	2.425535	-1.082098	-0.771105	0.363440
2	-0.085443	-0.923977	-0.699232	0.897274
3	-0.116032	-0.283703	-1.372355	-1.264006
4	-0.562175	1.200134	1.039529	0.492148
5	-0.070678	-0.661320	-0.416581	0.022234

`df.pct_change(periods=2)`

	0	1	2	3
0	NaN	NaN	NaN	NaN
1	NaN	NaN	NaN	NaN
2	-0.720087	1.535504	-1.857284	3.743931
3	-1.047838	-0.737821	0.779726	-4.477898
4	5.579538	-2.298878	-2.486674	-0.451508
5	-0.390876	1.331029	-0.696448	-1.017590

`pct_change` includes control over how missing data is imputed, how large a time-lag to use, etc. See documentation for more detail:

https://pandas.pydata.org/pandas-docs/stable/generated/pandas.Series.pct_change.html

Computing covariances

`cov` method computes covariance between a Series and another Series.

```
1 s1 = pd.Series(np.random.randn(1000))
2 s2 = pd.Series(0.1*s1+np.random.randn(1000))
3 s1.cov(s2)
```

```
0.1522727637202401
```

`cov` method is also supported by DataFrame, but instead computes a new DataFrame of covariances between columns.

	0	1	2	3
0	-0.305249	-0.364416	0.815636	0.189141
1	2.425535	-1.082098	-0.771105	0.363440
2	-0.085443	-0.923977	-0.699232	0.897274
3	-0.116032	-0.283703	-1.372355	-1.264006
4	-0.562175	1.200134	1.039529	0.492148
5	-0.070678	-0.661320	-0.416581	0.022234

```
1 df.cov()
```

	0	1	2	3
0	1.208517	-0.515225	-0.430870	0.093096
1	-0.515225	0.673964	0.520126	-0.021969
2	-0.430870	0.520126	0.911544	0.329498
3	0.093096	-0.021969	0.329498	0.546332

`cov` supports extra arguments for further specifying behavior:
<https://pandas.pydata.org/pandas-docs/stable/generated/pandas.Series.cov.html>

Pairwise correlations

```
1 df = pd.DataFrame(np.random.randn(1000, 5),  
2                   columns=['a', 'b', 'c', 'd', 'e'])  
3 df.corr(method='spearman')
```

DataFrame `corr` method computes correlations between columns (use `axis` keyword to change this behavior). `method` argument controls which correlation score to use (default is Pearson's correlation).

	a	b	c	d	e
a	1.000000	0.018325	-0.029441	0.002467	-0.048051
b	0.018325	1.000000	-0.000091	0.004212	-0.018435
c	-0.029441	-0.000091	1.000000	0.016103	0.034150
d	0.002467	0.004212	0.016103	1.000000	0.053519
e	-0.048051	-0.018435	0.034150	0.053519	1.000000

```
1 df.corr(method='kendall')
```

	a	b	c	d	e
a	1.000000	0.012264	-0.019075	0.001333	-0.032745
b	0.012264	1.000000	0.000212	0.002515	-0.012168
c	-0.019075	0.000212	1.000000	0.009630	0.022326
d	0.001333	0.002515	0.009630	1.000000	0.035872
e	-0.032745	-0.012168	0.022326	0.035872	1.000000

Ranking data

`rank` method returns a new Series whose values are the data ranks.

```
1 s = pd.Series(np.random.randn(5),
2               index=list('abcde'))
3 s
```

```
a    1.804688
b   -1.203916
c    1.055365
d   -0.048237
e    1.659330
dtype: float64
```

```
1 s.rank()
```

```
a    5.0
b    1.0
c    3.0
d    2.0
e    4.0
dtype: float64
```

Ties are broken by assigning the mean rank to both values.

```
1 s[0] = s[1] = 0
2 s.rank()
```

```
a    2.5
b    2.5
c    4.0
d    1.0
e    5.0
dtype: float64
```

Ranking data

By default, `rank` ranks columns of a DataFrame individually.

	0	1	2	3	4
0	-0.606576	-0.892385	0.891247	-0.280582	0.601239
1	-1.036933	0.905388	0.012123	-2.497602	0.501482
2	0.387677	0.850437	-1.578854	-0.263305	0.540390
3	-0.631557	-0.528819	0.561295	0.955113	0.980433

```
df.rank()
```

	0	1	2	3	4
0	3.0	1.0	4.0	2.0	3.0
1	1.0	4.0	2.0	1.0	1.0
2	4.0	3.0	1.0	3.0	2.0
3	2.0	2.0	3.0	4.0	4.0

Rank rows instead by supplying an `axis` argument.

```
df.rank(1)
```

	0	1	2	3	4
0	2.0	1.0	5.0	3.0	4.0
1	2.0	5.0	3.0	1.0	4.0
2	3.0	5.0	1.0	2.0	4.0
3	1.0	2.0	3.0	4.0	5.0

Note: more complicated ranking of whole rows (i.e., sorting whole rows rather than sorting columns individually) is possible, but requires we define an ordering on Series.

Aggregating data

```
1 tsdf = pd.DataFrame(np.random.randn(10, 3),  
2                       columns=['DOW', 'NASDAQ', 'S&P500'],  
3                       index=pd.date_range('1/1/2000', periods=10))  
4 tsdf.head()
```

	DOW	NASDAQ	S&P500
2000-01-01	1.118903	0.317094	-0.936392
2000-01-02	1.091083	0.828543	-1.961891
2000-01-03	-1.309894	-1.052207	0.256100
2000-01-04	0.654260	-0.527830	0.030650
2000-01-05	-1.041396	-0.559097	0.876613

This command creates time series data, with rows indexed by year-month-day timestamps.

Supplying a list of functions to `agg` will apply each function to each column of the DataFrame, with each function getting a row in the resulting DataFrame.

```
1 tsdf.agg([np.median, np.mean, np.std])
```

	DOW	NASDAQ	S&P500
median	0.534165	0.230327	-0.076018
mean	0.391512	0.159331	-0.239343
std	1.163320	0.907218	0.773417

`agg` is an alias for the method `aggregate`. Both work exactly the same.

Aggregating data

	DOW	NASDAQ	S&P500
2000-01-01	1.118903	0.317094	-0.936392
2000-01-02	1.091083	0.828543	-1.961891
2000-01-03	-1.309894	-1.052207	0.256100
2000-01-04	0.654260	-0.527830	0.030650
2000-01-05	-1.041396	-0.559097	0.876613

`agg` can, alternatively, take a dictionary whose keys are column names, and values are functions.

Note that the values here are strings, not functions! `pandas` supports dispatch on strings. It recognizes certain strings as referring to functions. `apply` supports similar behavior.

```
1 tsdf.agg({'DOW': 'mean',  
2         'NASDAQ': 'median',  
3         'S&P500': 'max'})
```

```
NASDAQ    0.230327  
S&P500    0.876613  
DOW       0.391512  
dtype: float64
```

Aggregating data

df contains mixed data types.

```
1 df = pd.DataFrame({'A': [1, 2, 3],  
2                     'B': [1., 2., 3.],  
3                     'C': ['foo', 'bar', 'baz']})  
4 df
```

	A	B	C
0	1	1.0	foo
1	2	2.0	bar
2	3	3.0	baz

agg (and similarly apply) will only try to apply these functions on the columns of types supported by those functions.

```
1 df.agg(['mean', 'max'])
```

Note: the DataFrame `transform` method provides generally similar functionality to the `agg` method.

	A	B	C
max	3.0	3.0	foo
mean	2.0	2.0	NaN

pandas doesn't know how to compute a mean string, so it doesn't try.

Iterating over Series and DataFrames

```
1 s
apple    fruit
cat      animal
goat     animal
banana   fruit
kiwi     fruit
dtype: object
```

```
1 for x in s:
2     print x
```

```
fruit
animal
animal
fruit
fruit
```

Iterating over a Series gets an iterator over the values of the Series.

Iterating over a DataFrame gets an iterator over the column names.

```
1 df
      A      B      C
0 -2.072339 -1.282539 -1.241128
1 -0.587874  0.517591 -0.394561
2 -0.164436  1.450398 -0.975424
3 -1.215576 -0.671235  0.394053
4 -0.350299  1.958805  0.467778
```

```
1 for x in df:
2     print x
```

```
A
B
C
```

Iterating over Series and DataFrames

```
1 for x in df.iteritems():  
2     print(x)
```

```
('A', 0    -2.072339  
1    -0.587874  
2    -0.164436  
3    -1.215576  
4    -0.350299  
Name: A, dtype: float64)  
( 'B', 0    -1.282539  
1     0.517591  
2     1.450398  
3    -0.671235  
4     1.958805  
Name: B, dtype: float64)  
( 'C', 0    -1.241128  
1    -0.394561  
2    -0.975424  
3     0.394053  
4     0.467778  
Name: C, dtype: float64)
```

`iteritem()` method is supported by both Series and DataFrames. Returns an iterator over the key-value pairs. In the case of Series, these are (index,value) pairs. In the case of DataFrames, these are (colname, Series) pairs.

1	df																								
	<table><thead><tr><th></th><th>A</th><th>B</th><th>C</th></tr></thead><tbody><tr><td>0</td><td>-2.072339</td><td>-1.282539</td><td>-1.241128</td></tr><tr><td>1</td><td>-0.587874</td><td>0.517591</td><td>-0.394561</td></tr><tr><td>2</td><td>-0.164436</td><td>1.450398</td><td>-0.975424</td></tr><tr><td>3</td><td>-1.215576</td><td>-0.671235</td><td>0.394053</td></tr><tr><td>4</td><td>-0.350299</td><td>1.958805</td><td>0.467778</td></tr></tbody></table>		A	B	C	0	-2.072339	-1.282539	-1.241128	1	-0.587874	0.517591	-0.394561	2	-0.164436	1.450398	-0.975424	3	-1.215576	-0.671235	0.394053	4	-0.350299	1.958805	0.467778

Iterating over Series and DataFrames

```
1 for x in df.iterrows():  
2     print(x)
```

```
(0, A    -2.072339  
B    -1.282539  
C    -1.241128  
Name: 0, dtype: float64)  
(1, A    -0.587874  
B     0.517591  
C    -0.394561  
Name: 1, dtype: float64)  
(2, A    -0.164436  
B     1.450398  
C    -0.975424  
Name: 2, dtype: float64)  
(3, A    -1.215576  
B    -0.671235  
C     0.394053  
Name: 3, dtype: float64)  
(4, A    -0.350299  
B     1.958805  
C     0.467778  
Name: 4, dtype: float64)
```

DataFrame `iterrows()` returns an iterator over the rows of the DataFrame as (index, Series) pairs.

1	df		
	A	B	C
0	-2.072339	-1.282539	-1.241128
1	-0.587874	0.517591	-0.394561

3	-1.215576	-0.671235	0.394053
4	-0.350299	1.958805	0.467778

Iterating over Series and DataFrames

```
1 for x in df.iterrows():  
2     print(x)
```

```
(0, A    -2.072339  
B    -1.282539  
C    -1.241128  
Name: 0, dtype: float64)  
(1, A    -0.587874  
B     0.517591  
C    -0.394561  
Name: 1, dtype: float64)  
(2, A    -0.164436  
B     1.450398  
C    -0.975424  
Name: 2, dtype: float64)  
(3, A    -1.215576  
B    -0.671235  
C     0.394053  
Name: 3, dtype: float64)  
(4, A    -0.350299  
B     1.958805  
C     0.467778  
Name: 4, dtype: float64)
```

DataFrame `iterrows()` returns an iterator over the rows of the DataFrame as (index, Series) pairs.

```
1 df
```

Note: DataFrames are designed to make certain operations (mainly vectorized operations) fast. This implementation has the disadvantage that iteration over a DataFrames is slow. It is usually best to avoid iterating over the elements of a DataFrame or Series, and instead find a way to compute your quantity of interest using a vectorized operation or a map/reduce operation.

```
4 -0.350299  1.958805  0.467778
```

Group By: reorganizing data

“Group By” operations are a concept from databases

- Splitting data based on some criteria

- Applying functions to different splits

- Combining results into a single data structure

Fundamental object: `pandas` `GroupBy` objects

Group By: reorganizing data

```
1 df = pd.DataFrame({'A' : ['plant', 'animal', 'plant', 'plant'],
2                     'B' : ['apple', 'goat', 'kiwi', 'grape'],
3                     'C' : np.random.randn(4),
4                     'D' : np.random.randn(4)})
5 df
```

	A	B	C	D
0	plant	apple	0.529326	-0.796997
1	animal	goat	-0.901377	-0.670747
2	plant	kiwi	1.203032	1.162924
3	plant	grape	-0.740208	1.184488

DataFrame groupby method
returns a pandas groupby object.

```
1 df.groupby('A')
```

```
<pandas.core.groupby.DataFrameGroupBy object at 0x11fe88bd0>
```

Group By: reorganizing data

	A	B	C	D
0	plant	apple	0.529326	-0.796997
1	animal	goat	-0.901377	-0.670747
2	plant	kiwi	1.203032	1.162924
3	plant	grape	-0.740208	1.184488

Every `groupby` object has an attribute `groups`, which is a dictionary with maps group labels to the indices in the DataFrame.

```
1 df.groupby('A')
```

```
<pandas.core.groupby.DataFrameGroupBy object at 0x11fe88bd0>
```

```
1 df.groupby('A').groups
```

```
{'animal': Int64Index([1], dtype='int64'),  
'plant': Int64Index([0, 2, 3], dtype='int64')}
```

In this example, we are splitting on the column 'A', which has two values: 'plant' and 'animal', so the groups dictionary has two keys.

Group By: reorganizing data

	A	B	C	D
0	plant	apple	0.529326	-0.796997
1	animal	goat	-0.901377	-0.670747
2	plant	kiwi	1.203032	1.162924
3	plant	grape	-0.740208	1.184488

Every `groupby` object has an attribute `groups`, which is a dictionary with maps group labels to the indices in the DataFrame.

The important point is that the `groupby` object is storing information about how to partition the rows of the original DataFrame according to the argument(s) passed to the `groupby` method.

```
1 df.groupby('A')
```

```
<pandas.core.groupby.DataFrameGroupBy
```

```
1 df.groupby('A').groups
```

```
{'animal': Int64Index([1], dtype='int64'),  
'plant': Int64Index([0, 2, 3], dtype='int64')}
```

In this example, we are splitting on the column 'A', which has two values: 'plant' and 'animal', so the groups dictionary has two keys.

Group By: aggregation

	A	B	C	D
0	plant	apple	0.529326	-0.796997
1	animal	goat	-0.901377	-0.670747
2	plant	kiwi	1.203032	1.162924
3	plant	grape	-0.740208	1.184488

```
1 df.groupby('A').mean()
```

	C	D
A		
animal	-0.901377	-0.670747
plant	0.330717	0.516805

Split on group 'A', then compute the means within each group. Note that columns for which means are not supported are removed, so column 'B' doesn't show up in the result.

Group By: aggregation

```
1 arrs = [['math', 'math', 'econ', 'econ', 'stats', 'stats'],
2         ['left', 'right', 'left', 'right', 'left', 'right']]
3 index = pd.MultiIndex.from_arrays(arrs, names=['major', 'handedness'])
4 s = pd.Series(np.random.randn(6), index=index)
5 s
```

```
major handedness
math left -2.015677
right 0.537438
econ left 1.071951
right -0.504158
stats left 1.204159
right -0.288676
dtype: float64
```

Here we're building a hierarchically-indexed Series (i.e., multi-indexed), recording (fictional) scores of students by major and handedness.

Suppose I want to collapse over handedness to get average scores by major. In essence, I want to group by major and ignore handedness.

Group By: aggregation

```
major handedness
math left -2.015677
right 0.537438
econ left 1.071951
right -0.504158
stats left 1.204159
right -0.288676
dtype: float64
```

Suppose I want to collapse over handedness to get average scores by major. In essence, I want to group by major and ignore handedness.

Group by the 0-th level of the hierarchy (i.e., 'major'), and take means.

```
1 s.groupby(level=0).mean()
```

```
major
econ 0.283897
math -0.739120
stats 0.457741
dtype: float64
```

We could have equivalently written `groupby('major')`, here.

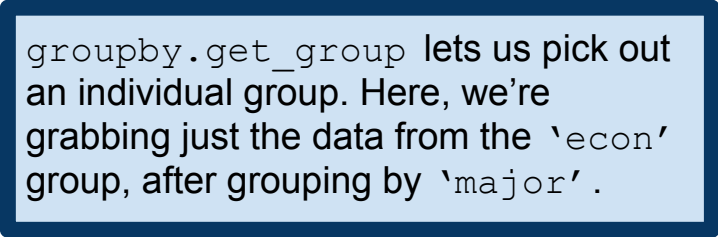

Group By: examining groups

```
1 s
```

```
major handedness
math left -2.015677
right 0.537438
econ left 1.071951
right -0.504158
stats left 1.204159
right -0.288676
dtype: float64
```

```
1 s.groupby('major').get_group('econ')
```

```
major handedness
econ left 1.071951
right -0.504158
dtype: float64
```

`groupby.get_group` lets us pick out an individual group. Here, we're grabbing just the data from the 'econ' group, after grouping by 'major'.

Group By: aggregation

Similar aggregation to what we did a few slides ago, but now we have a DataFrame instead of a Series.

		A	B
major	handedness		
math	left	1	-0.856890
	right	1	0.425160
econ	left	1	-0.707796
	right	1	-1.944487
stats	left	2	0.341265
	right	2	-0.938632
phys	left	3	-0.960931
	right	3	1.423622

```
1 df.groupby('handedness').mean()
```

	A	B
handedness		
left	1.75	-0.546088
right	1.75	-0.258584

Group By: aggregation

Similar aggregation to what we did a few slides ago, but now we have a DataFrame instead of a Series.

Groupby objects also support the `aggregate` method, which is often more convenient.

```
1 g = df.groupby('handedness')  
2 g.aggregate(np.sum)
```

	A	B
handedness		
left	7	-2.184352
right	7	-1.034337

		A	B
major handedness			
math	left	1	-0.856890
	right	1	0.425160
econ	left	1	-0.707796
	right	1	-1.944487
stats	left	2	0.341265
	right	2	-0.938632
phys	left	3	-0.960931
	right	3	1.423622

```
1 df.groupby('handedness').mean()
```

	A	B
handedness		
left	1.75	-0.546088
right	1.75	-0.258584

Transforming data

From the documentation: “The transform method returns an object that is indexed the same (same size) as the one being grouped.”

```
1 index = pd.date_range('10/1/1999', periods=1100)
2 ts = pd.Series(np.random.normal(0.5, 2, 1100), index)
3 ts.head()
```

```
1999-10-01    -1.283451
1999-10-02     0.468645
1999-10-03     2.796156
1999-10-04     0.449197
1999-10-05     1.647331
Freq: D, dtype: float64
```

Building a time series,
indexed by year-month-day.

Suppose we want to
standardize these scores
within each year.

```
1 key = lambda d: d.year
2 zscore = lambda x: (x - x.mean()) / x.std()
3 transformed = ts.groupby(key).transform(zscore)
4 transformed.head()
```

```
1999-10-01    -1.097395
1999-10-02    -0.243334
1999-10-03     0.891214
1999-10-04    -0.252814
1999-10-05     0.331218
Freq: D, dtype: float64
```

Group the data according to the output
of the key function, apply the given
transformation within each group, then
un-group the data.

Important point: the result of `groupby.transform` has
the same dimension as the original DataFrame or Series.

Filtering data

```
1 sf = pd.Series([1, 1, 2, 2, 3, 3])
2 sf
```

```
0    1
1    1
2    2
3    2
4    3
5    3
dtype: int64
```

```
1 sf.groupby(sf).filter(lambda x: x.sum() > 2)
```

```
2    2
3    2
4    3
5    3
dtype: int64
```

From the documentation: “The argument of filter must be a function that, applied to the group as a whole, returns True or False.”

So this will throw out all the groups with sum ≤ 2 .

Like transform, the result is ungrouped.

Combining DataFrames

```
1 df1 = pd.DataFrame({'A':np.random.randn(4),  
2                      'B':np.random.randn(4),  
3                      'C':np.random.randn(4)},  
4                      index=[0,1,2,3])  
5 df2 = pd.DataFrame({'A':np.random.randn(4),  
6                      'B':np.random.randn(4)},  
7                      index=[3,4,5,6])  
8 pd.concat([df1,df2])
```

pandas concat function concatenates DataFrames into a single DataFrame.

Repeated indices remain repeated in the resulting DataFrame.

pandas.concat accepts numerous optional arguments for finer control over how concatenation is performed. See the documentation for more.

	A	B	C
0	0.755669	1.497149	0.889586
1	-0.197404	0.674905	1.131785
2	0.341409	0.632993	0.495411
3	0.646052	-0.809168	-0.708263
3	0.508306	-0.070561	NaN
4	1.172885	-0.518003	NaN
5	-0.103887	-0.479715	NaN
6	0.596387	-2.156612	NaN

Missing values get NaN.

Merges and joins

`pandas` DataFrames support many common database operations
Most notably, join and merge operations

We'll learn about these when we discuss SQL later in the semester
So we won't discuss them here

Important: What we learn for SQL later has analogues in `pandas`

If you are already familiar with SQL, you might like to read this:
https://pandas.pydata.org/pandas-docs/stable/comparison_with_sql.html

Pivoting and Stacking

	date	variable	value
0	2000-01-03	A	1.234594
1	2000-01-04	A	0.661894
2	2000-01-05	A	0.810323
3	2000-01-03	B	-0.156366
4	2000-01-04	B	0.798020
5	2000-01-05	B	-0.360506
6	2000-01-03	C	0.375464
7	2000-01-04	C	0.413346
8	2000-01-05	C	-0.071480
9	2000-01-03	D	0.108641
10	2000-01-04	D	-0.738962
11	2000-01-05	D	0.460154

Data in this format is usually called **stacked**. It is common to store data in this form in a file, but once it's read into a table, it often makes more sense to create columns for A, B and C. That is, we want to **unstack** this DataFrame.

Pivoting and Stacking

	date	variable	value
0	2000-01-03	A	1.234594
1	2000-01-04	A	0.661894
2	2000-01-05	A	0.810323
3	2000-01-03	B	-0.156366
4	2000-01-04	B	0.798020
5	2000-01-05	B	-0.360506
6	2000-01-03	C	0.375464
7	2000-01-04	C	0.413346
8	2000-01-05	C	-0.071480
9	2000-01-03	D	0.108641
10	2000-01-04	D	-0.738962
11	2000-01-05	D	0.460154

The `pivot` method takes care of unstacking DataFrames. We supply indices for the new DataFrame, and tell it to turn the variable column in the old DataFrame into a set of column names in the unstacked one.

```
1 df.pivot(index='date',  
2         columns='variable',  
3         values='value')
```

variable	A	B	C	D
date				
2000-01-03	1.234594	-0.156366	0.375464	0.108641
2000-01-04	0.661894	0.798020	0.413346	-0.738962
2000-01-05	0.810323	-0.360506	-0.071480	0.460154

Pivoting and Stacking

Note: we could also construct the index set `tuples` using `itertools`.

```
1 tuples = list(zip(*[['bird', 'bird', 'goat', 'goat'],
2                     ['x', 'y', 'x', 'y']]))
3 index = pd.MultiIndex.from_tuples(tuples, names=['animal', 'cond'])
4 df = pd.DataFrame(np.random.randn(4, 2),
5                   index=index, columns=['A', 'B'])
6 df
```

How do we stack this? That is, how do we get a non-pivot version of this DataFrame? The answer is to use the DataFrame `stack` method.

		A	B
bird	cond		
	x	0.699732	-1.407296
goat	y	0.810211	1.249299
	x	-0.909280	0.184450
	y	-0.755891	-0.957222

Pivoting and Stacking

		A	B
animal	cond		
bird	x	0.699732	-1.407296
	y	0.810211	1.249299
goat	x	-0.909280	0.184450
	y	-0.755891	-0.957222

The DataFrame `stack` method makes a stacked version of the calling DataFrame. In the event that the resulting column index set is trivial, the result is a Series. Note that `df.stack()` no longer has columns A or B. The column labels A and B have become an extra index.

```
1 df.stack()

animal cond
bird    x    A    0.699732
        x    B   -1.407296
        y    A    0.810211
        y    B    1.249299
goat    x    A   -0.909280
        x    B    0.184450
        y    A   -0.755891
        y    B   -0.957222

dtype: float64
```

```
1 s = df.stack()
2 s['bird']['x']['A']

0.69973202218227948
```

Pivoting and Stacking

```
1 columns = pd.MultiIndex.from_tuples(  
2     [('A', 'cat', 'long'), ('B', 'cat', 'long'),  
3     ('A', 'dog', 'short'), ('B', 'dog', 'short')],  
4     names=['cond', 'animal', 'hair_length'])  
5 df = pd.DataFrame(np.random.randn(4, 4), columns=columns)  
6 df
```

cond	A	B	A	B
animal	cat	cat	dog	dog
hair_length	long	long	short	short
0	-0.424446	-0.204965	-2.494808	1.278635
1	-0.710625	-0.801063	0.947879	0.763564
2	0.016435	0.701775	-0.577844	-1.315433
3	0.451242	0.886683	-0.864094	0.529257

Here is a more complicated example. Notice that the column labels have a three-level hierarchical structure.

There are multiple ways to stack this data. At one extreme, we could make all three levels into columns. At the other extreme, we could choose only one to make into a column.

Pivoting and Stacking

Stack only according to level 1
(i.e., the animal column index).

Missing animal x cond x hair_length
conditions default to NaN.

cond	A	B	A	B
animal	cat	cat	dog	dog
hair_length	long	long	short	short
0	-0.424446	-0.204965	-2.494808	1.278635
1	-0.710625	-0.801063	0.947879	0.763564

Pivoting and Stacking

```
1 df.stack(level=[0,1,2])
```

	cond	animal	hair_length	
0	A	cat	long	-0.424446
		dog	short	-2.494808
	B	cat	long	-0.204965
		dog	short	1.278635
1	A	cat	long	-0.710625
		dog	short	0.947879
	B	cat	long	-0.801063
		dog	short	0.763564
2	A	cat	long	0.016435
		dog	short	-0.577844
	B	cat	long	0.701775
		dog	short	-1.315433
3	A	cat	long	0.451242
		dog	short	-0.864094
	B	cat	long	0.886683
		dog	short	0.529257

dtype: float64

cond	A	B	A	B
animal	cat	cat	dog	dog
hair_length	long	long	short	short
0	-0.424446	-0.204965	-2.494808	1.278635
1	-0.710625	-0.801063	0.947879	0.763564
2	0.016435	0.701775	-0.577844	-1.315433
3	0.451242	0.886683	-0.864094	0.529257

Stacking across all three levels yields a Series, since there is no longer any column structure. This is often called **flattening** a table.

Notice that the NaN entries are not necessary here, since we have an entry in the Series only for entries of the original DataFrame.

Plotting DataFrames

```
1 df = pd.DataFrame(np.random.randn(1000, 3),
2                   index=pd.date_range('1/1/2000', periods=1000),
3                   columns=['cat', 'bird', 'goat'])
4 df = df.cumsum()
5 _ = df.plot()
```

cumsum gets partial sums,
just like in numpy.

Note: this requires that you
have imported matplotlib.

Note that legend is automatically
populated and x-ticks are
automatically date formatted.
