Abstract
It has been shown that graphical models can be used to leverage the dependence in large-scale multiple testing problems with significantly improved performance (Sun & Cai, 2009; Liu et al., 2012). These graphical models are fully parametric and require that we know the parameterization of \( f_1 \) — the density function of the test statistic under the alternative hypothesis. However in practice, \( f_1 \) is often heterogeneous, and cannot be estimated with a simple parametric distribution. We propose a novel semiparametric approach for multiple testing under dependence, which estimates \( f_1 \) adaptively. This semiparametric approach exactly generalizes the local FDR procedure (Efron et al., 2001) and connects with the BH procedure (Benjamini & Hochberg, 1995). A variety of simulations show that our semiparametric approach outperforms classical procedures which assume independence and the parametric approaches which capture dependence.

1. Introduction
High-throughput computational biology studies, such as gene expression analysis and genome-wide association studies, often involve large-scale multiple testing problems which exhibit dependence in the sense that whether the null hypothesis of one test is true or not depends on the ground truth of other tests. Recently, new multiple testing procedures have been proposed with such dependence explicitly captured by graphical models such as hidden Markov models (Sun & Cai, 2009) and Markov-random-field-coupled mixture models (Liu et al., 2012). These graphical models are fully parametric, and they assume that we know not only the parameterization form of \( f_0 \), but also the parameterization form of \( f_1 \). Eventually, a fully parametric graphical model is learned, and the multiple testing problem becomes an inference problem on the graphical model. This parametric approach is effective in some simple situations, but the assumptions for \( f_1 \) often make it impractical, as discussed next.

A long tradition in hypothesis testing is to derive test statistics and calculate \( P \)-values all under the null hypothesis \( H_0 \). The distribution of the test statistic under \( H_1 \) sometimes can be difficult to derive. Take for instance a two-proportion \( z \)-test, which tests whether two Bernoulli variables have the same parameter (i.e. \( P(\text{head}) \)) in coinflippings; the two-proportion \( z \)-test is widely used in case-control studies (e.g. comparing the minor allele frequencies in cases and controls). Under \( H_0 \) (the two proportions are the same), the test statistic \( X \) asymptotically follows a standard normal \( \mathcal{N}(0, 1) \). Under \( H_1 \) (the two proportions are different), \( X \) asymptotically follows a standardized non-centered normal \( \mathcal{N}(\mu, 1) (\mu \neq 0) \) where \( \mu \) depends on the odds-ratio of this genetic marker. When there are multiple genetic markers to be tested, \( f_0 \) remains \( \mathcal{N}(0, 1) \), but \( f_1 \) becomes a mixture of Gaussians because these associated markers can have different odds-ratios and therefore

---

1. \( f_0 \) and \( f_1 \) are the probability density functions of the test statistic under the null hypothesis \( H_0 \) and the alternative hypothesis \( H_1 \), respectively. In the HMM model (Sun & Cai, 2009) and the MRF-coupled mixture model (Liu et al., 2012), \( f_0 \) and \( f_1 \) are the emitting probabilities for state 0 and state 1 respectively.
different \( \mu \) values (i.e. different effect sizes). In this situation, \( f_1 \) is no longer a simple parametric distribution. In a real-world genome-wide association study on breast cancer, we plot the estimated \( f_1 \) in Figure 1; obviously it is inappropriate to estimate \( f_1 \) with a simple parametric distribution. Note that this is not a problem for classical multiple testing procedures such as the BH procedure, whose calculations of \( P \)-values are done under \( H_0 \), but this is a serious problem for the graphical-model-based procedures which require \( f_1 \) to be estimated parametrically. Therefore, the key question is whether we can still make use of the graphical models to leverage the dependence among the hypotheses without making assumptions about \( f_1 \).

In this paper, we propose a semiparametric graphical model to leverage the dependence among the hypotheses. In our model, \( f_1 \) is estimated nonparametrically and the remaining parts are estimated parametrically. More algorithmic details are introduced in Section 3 after we summarize the terminology in Section 2. Section 4 shows that the two widely-used multiple testing procedures, the BH procedure (Benjamini & Hochberg, 1995) and the local FDR procedure (Efron et al., 2001), estimate their parameters in the same semiparametric way to avoid assumptions about \( f_1 \). This unification demonstrates that the most appropriate way of using graphical models to capture the dependence is the semiparametric model in our paper rather than the fully parametric models (Sun & Cai, 2009; Liu et al., 2012). Simulations in Section 5 show that our semiparametric approach controls false discovery rate and reduces false non-discovery rate, compared with the baseline procedures. We apply the procedure to a real-world genome-wide association study on breast cancer in Section 6 and identify a number of genetic variants.

2. Preliminaries

**FDR, FNR, Validity and Efficiency:** When we test \( m \) hypotheses simultaneously, various outcomes can be described by Table 1 based on their ground truth and whether the hypotheses are rejected. False discovery rate (FDR), \( E(N_0/R|R>0)P(R>0) \), is the expected proportion of incorrectly rejected null hypotheses (Benjamini & Hochberg, 1995). False non-discovery rate (FNR), \( \frac{E(N_0/N_0+S)}{m} \), is the expected proportion of false non-rejections in those tests whose null hypotheses are not rejected (Genovese & Wasserman, 2002). An FDR procedure is valid if it controls FDR at a nominal level \( \alpha \). One valid procedure is more efficient than another if it has a smaller FNR. In multiple testing problems, we would like to control FDR at the nominal level and reduce FNR as much as possible.

**Dependence in Multiple Testing:** Classical multiple testing procedures usually assume independence among the hypotheses. The effects of dependence on multiple testing have been investigated with a focus on the validity issue, namely how to control FDR at the nominal level when dependence exists (Benjamini & Yekutieli, 2001; Finner & Roters, 2002; Reiner et al., 2003; Owen, 2005; Sarkar, 2006; Efron, 2007; Farcomeni, 2007; Romano et al., 2008; Strimmer, 2008; Wu, 2008; Blanchard & Roquain, 2009). Despite FDR-control challenges, dependence also brings opportunities for decreasing FNR. This efficiency issue has been investigated (Yekutieli & Benjamini, 1999; Genovese et al., 2006; Benjamini & Heller, 2007; Zhang et al., 2011), indicating FNR could be decreased by leveraging the dependence among hypotheses. Several approaches have been proposed, such as dependence kernels (Leek & Storey, 2008), factor models (Friguet et al., 2009) and principal factor approximation (Fan et al., 2012). Sun & Cai (2009) use a hidden Markov model to explicitly leverage chain dependence structures (Sun & Cai, 2009). Liu et al. (2012) extend such graphical-model-based approaches to general dependence structures via a Markov-random-field-coupled mixture model. Capturing the dependence in multiple testing in such an explicit manner is innovative, but it relies on the strong assumption that we know the parameterization of \( f_1 \), which is unrealistic in all but the simplest situations. Improper assumption of \( f_1 \) may make the testing procedure too liberal, e.g. Figure 4 of Sun & Cai (2009), or conservative, e.g. Figure 3 of Liu et al. (2012). In this paper, we build on the approach of Liu et al. (2012) and take the major step of relaxing this assumption by estimating \( f_1 \) adaptively.

### 3. Methods

#### 3.1. Graphical models for Multiple Testing

Let \( x = (x_1, ..., x_m) \) be a vector of test statistics from hypotheses \((H_1, ..., H_m)\) with their ground truth denoted by a latent Bernoulli vector \( \theta = (\theta_1, ..., \theta_m) \in \{0, 1\}^m \).
with \(\theta_i = 0\) denoting that the hypothesis \(H_i\) is null and \(\theta_i = 1\) denoting that the hypothesis \(H_i\) is non-null. In the work of Liu et al. (2012), the dependence among these hypotheses is represented as a binary Markov random field (MRF) on \(\theta\). The structure of the MRF is assumed to be known, and described by an undirected graph \(G(\mathcal{V}, \mathcal{E})\) with the node set \(\mathcal{V}\) and the edge set \(\mathcal{E}\). The dependence between \(H_i\) and \(H_j\) is denoted by an edge connecting node \(i\) and node \(j\). The strength of dependence is captured by a potential function (parametrized by \(\phi_{ij}, 0 < \phi_{ij} < 1\)) on this edge. The degree of prior belief that \(H_i\) is null is captured by the node potential function (parametrized by \(\pi_i, 0 < \pi_i < 1\)). Suppose that the probability density function of the test statistic \(x_i|\theta_i = 0\) is \(f_0\), and the density of \(x_i|\theta_i = 1\) is \(f_1\). Then \((x, \theta, \pi, \phi, f_0, f_1)\) forms an MRF-coupled mixture model where \(\pi\) and \(\phi\) are node potential functions and edge potential functions in the MRF. In the MRF-coupled mixture model, \(x\) is observed, and \(\theta\) is hidden. We also need to estimate \(\pi\), \(\phi\) and \(f_1\).  

For the reasons discussed in Section 1, it is often difficult to estimate \(f_1\) with a simple parametric distribution. In order to avoid the \(f_1\) assumption, we estimate \(f_1\) adaptively via an indirect, nonparametric way, as introduced in Section 3.2. Then we estimate \(\pi\) and \(\phi\) via a contrastive divergence style algorithm, as introduced in Section 3.3. Therefore the graphical model is learned semiparametrically — \(f_1\) is learned nonparametrically and the MRF part is learned by estimating parameters \(\phi\) and \(\pi\). Finally, we perform marginal inference of \(\theta|x\) with the learned model and reject hypotheses with a step-up procedure to control FDR, as introduced in Section 3.4. Figure 2 \(^3\) shows the semiparametric MRF-coupled mixture model for the three dependent hypotheses \(H_i, H_j\) and \(H_k\).

3.2. Nonparametric Estimation of \(f_1\)

We cannot directly estimate \(f_1\) from observed \(x\) because the ground truth \(\theta\) is hidden. However, we can estimate \(f\) from observed \(x\) nonparametrically via kernel density estimation. Therefore, we can estimate \(f_1\) indirectly using the rule of total probability

\[
f(x) = p_0 f_0(x) + (1 - p_0) f_1(x),
\]

where \(p_0\) is the proportion of null hypotheses. Since we know \(f_0\) in advance (e.g. \(N(0, 1)\)), we only need to estimate \(f\) and \(p_0\) so as to estimate \(f_1\).

**Estimating \(p_0\):** We can estimate \(p_0\) with the method in the work of Storey (2002), namely

\[
\hat{p}_0(\lambda) = \frac{W(\lambda)}{(1 - \lambda)m}
\]

where \(\lambda \in [0, 1]\) is a tuning parameter, and \(W(\lambda)\) is the total number of hypotheses whose \(P\)-values are above \(\lambda\). The motivation of this estimation is that the \(P\)-values of null hypotheses are uniformly distributed on the interval (0, 1). If we assume all the hypotheses with \(P\)-values greater than \(\lambda\) are from null hypotheses, then \(W(\lambda)/(1 - \lambda)\) is the total number of null hypotheses. Therefore the right hand side of (2) is an estimate of \(p_0\). Obviously, \(\hat{p}_0(\lambda)\) overestimates \(p_0\) because there might be nonnull hypotheses whose \(P\)-values are greater than \(\lambda\), especially when \(\lambda\) is small. Therefore, a bias-variance trade-off presents in the choice of \(\lambda\) — a larger \(\lambda\) value yields less bias but brings in more variance. Storey et al. (2004) showed that the BH procedure coupled with \(\hat{p}_0(\lambda)\) maintains strong control of FDR under mild conditions. In simulations, we test different \(\lambda\) values, and the results show that the performance of our multiple testing procedure is insensitive to different choices of \(\lambda\).

**Estimating \(f\):** Since we can observe all the test statistics \(x\), we can estimate \(f\) directly via kernel density estimation (Rosenblatt, 1956). One may choose any kernel function and bandwidth parameter as long as they provide a reasonable estimate. A Gaussian kernel would be a natural choice. Nevertheless in our experiments, we use the Epanechnikov kernel because its computation burden is low, and it is optimal in a minimum variance sense (Epanechnikov, 1969). Finally we can get \(\hat{f}\), the nonparametric estimate of \(f\).

**Estimating \(f_1\):** With the estimated \(\hat{p}_0\) and \(\hat{f}\), we estimate \(f_1\) as

\[
\hat{f}_1(x) = \frac{\hat{f}(x) - \hat{p}_0 f_0(x)}{1 - \hat{p}_0}.
\]
3.3. Parametric Estimation of $\phi$ and $\pi$

The pairwise potential functions $\phi$ and the node potential functions $\pi$ parametrize the Markov random field part of the model. In the simulations, we tie all the pairwise potential functions together, i.e. $\phi=\{\phi\}$. In the real-world application in Section 6, we assume there are three types of edges (high correlation edges, medium correlation edges and low correlation edges), and there are three parameters, $\phi=\{\phi_h, \phi_m, \phi_l\}$, corresponding to the three levels of correlation. We also tie all the node potentials in both the simulations and the real-world application, i.e. $\pi=\{\pi\}$.

Parameter learning for MRFs is generally difficult due to the partition function. So far, the state-of-the-art parameter learning algorithms are based on contrastive divergence (Hinton, 2002), such as the persistent contrastive divergence (PCD) algorithm (Tieleman, 2008). Contrastive divergence algorithms are iterative algorithms which gradually update parameters by generating particles based on current estimates of parameters and then comparing the moments from the particles with the moments from the data. Contrastive divergence is related to pseudo-likelihood (Besag, 1975) and ratio matching (Hyvärinen, 2007a;b). However, contrastive divergence algorithms cannot be directly applied to our model because $\theta$ is hidden. Therefore, we modify the PCD algorithm as follows. Suppose we already generate particles for $\theta$ in the normal PCD algorithm. We further generate the particles for $x$ using $f_0$ and $f_1$ conditional on the generated particles for $\theta$. Then we update the parameters by comparing the moments from particles for $x$ and the moments from the observed $x$. One systematic review of learning parameters in hidden Markov random fields is in the prior work of Liu et al. (2014).

3.4. Inference of $\theta$ and FDR Control

After we estimate $f_1$, $\phi$ and $\pi$, the MRF-coupled mixture model is fully specified, and the next importance step is to calculate the posterior probability that $H_i$ is null given all the observed statistics $x$, namely $P(\theta_i=0|x)$ for $i=1, \ldots, m$. This quantity is termed the local index of significance (LIS) (Sun & Cai, 2009), which reduces to local false discovery rate $P(\theta_i=0|x_i)$ when the hypotheses are independent. In our simulations and the real-world application, we use a Markov chain Monte Carlo (MCMC) algorithm to perform posterior inference for $P(\theta_i=0|x)$.

After we calculate the posterior marginal probabilities of $\theta$ (i.e. LIS), we use a step-up procedure (Sun & Cai, 2009) to decide which of the hypotheses should be rejected so as to control FDR at the nominal level $\alpha$. We first sort LIS from the smallest value to the largest value. Suppose $\text{LIS}_1$, $\text{LIS}_2$, ..., and $\text{LIS}_m$ are the ordered LIS, and the corresponding hypotheses are $H_{(1)}$, $H_{(2)}$, ..., and $H_{(m)}$. Let

$$k = \max \left\{ i : \frac{1}{i} \sum_{j=1}^{i} \text{LIS}_j \leq \alpha \right\}. \quad (4)$$

Then we reject $H_{(i)}$ for $i = 1, \ldots, k$.

4. Connections with Classical Multiple Testing Procedures

We show that both the local FDR procedure (Efron et al., 2001) and the BH procedure (Benjamini & Hochberg, 2000; Genovese & Wasserman, 2004) can be regarded as semiparametric graphical models which do not consider dependence among the hypotheses. The local FDR procedure uses Bayes Theorem to calculate the posterior probability that $H_i$ is null given its observed test statistic $x_i$, namely

$$P(H_i \text{ is null} | X_i=x_i) = \frac{p_0 f_0(x_i)}{p_0 f_0(x_i) + p_1 f_1(x_i)}. \quad (5)$$

This posterior probability is termed the local false discovery rate (Efron & Tibshirani, 2002). Note that our LIS reduces to local false discovery rate under the assumption of independence. Efron & Tibshirani (2002) recommend using empirical Bayes inference (Robbins, 1956) to calculate local false discovery rate as

$$P(H_i \text{ is null} | X_i=x_i) = \frac{\hat{p}_0 f_0(x_i)}{f(x_i)}, \quad (6)$$

where $f$ is the empirical density of the test statistic and $\hat{p}_0$ is an estimate of $p_0$. If we use $\theta_i$ to denote the ground truth of $H_i$, its local false discovery rate is $P(\theta_i=0|X_i=x_i)$. Therefore, we can use the graphical model in Figure 3(a) to denote it. Obviously, this model is exactly our semiparametric model in Figure 2, except that there are no pairwise potentials capturing the dependence because the local FDR procedure assumes independence among the hypotheses. The model for the local FDR procedure is also semiparametric because $f_1$ is nonparametrically estimated. Also note that the parameter $\pi$ in our model reduces to the prior parameter $p_0$ in this simplified model.

The following shows that the BH procedure is also a semiparametric model, but the observed statistic is modeled by a cumulative distribution function (CDF). Let $P(1)<\ldots<P(m)$ be the ordered $P$-values from the $m$ tests and $P(0)=0$. The BH procedure rejects any hypothesis whose $P$-value satisfies $P \leq P^*$ with

$$P^* = \max \{ P_{(i)} | P_{(i)} \leq \frac{i \alpha}{m p_0} \}, \quad (7)$$
The local FDR procedure

The BH procedure

Figure 3. The plate presentation of the semiparametric graphical models for local FDR and the BH procedure.

which controls FDR at the level $\alpha$ (Benjamini & Hochberg, 1995; Storey, 2002; Genovese & Wasserman, 2002). The inequality in (7) can be rewritten as

$$\frac{p_0 P(i)}{i/m} \leq \alpha.$$  

(8)

Because a $P$-value is the CDF of $f_0$ at the value of its test statistic $x$, and $i/m$ is the empirical CDF of $f$ at the test statistic of $H(i)$, (8) is further rewritten as

$$\frac{p_0 F_0(x)}{F(x)} \leq \alpha,$$  

(9)

where $F_0$ and $F$ are the CDFs of $f_0$ and $f$ respectively, and $F$ is an empirical version of $F$. Note that the left hand side of (9) is also an empirical Bayes inference, similar to (6). Therefore, both the BH procedure and the local FDR procedure can be interpreted as empirical Bayes inference, and the difference is that the BH procedure uses the CDFs whereas the local FDR procedure uses the density functions. Thus, we can present the BH procedure as the graphical model in Figure 3(b). This model is also semiparametric because $F_1$ is nonparametrically estimated. Therefore, both the local FDR procedure and the BH procedure are semiparametric graphical models which do not consider dependence among the hypotheses.

5. Simulations

We explore the empirical performance of our multiple testing procedure and three baseline procedures, including the local FDR procedure (Efron et al., 2001), the BH procedure (Benjamini & Hochberg, 2000; Genovese & Wasserman, 2004) and the procedure based on a parametric graphical model (Liu et al., 2012). Because we have the ground truth parameters, we have two versions of our multiple testing approach, namely an oracle procedure and a data-driven procedure. The oracle procedure knows the true parameters in the graphical model (including $\phi$, $\pi$ and $f_1$), whereas the data-driven procedure does not and has to estimate the graphical model in the semiparametric way introduced in Sections 3.2 and 3.3. Both the BH procedure and the local FDR procedure need an estimate of $p_0$; we use the same estimating method in Section 3.2 for a fair comparison. The local FDR procedure also needs an estimate of $f$, and we estimate it in the same way as in our data-driven procedure.

We choose the setup to be consistent with previous work (Sun & Cai, 2009; Liu et al., 2012) when possible. We consider two dependence structures, namely a chain structure and a grid structure. For the chain structure, we choose the number of hypotheses $m=10,000$. For the grid structure, we choose a $100 \times 100$ grid, which also yields 10,000 hypotheses. We test two levels of dependence strength, i.e. $\phi=0.8$ and $\phi=0.6$. We set $\pi$ to be 0.4. We first simulate the ground truth of the hypotheses $\theta$ from $P(\theta; \phi, \pi)$ and then simulate the test statistics $x$ from $P(x|\theta; f_0, f_1)$. We assume that the observed $x_i$ under the null hypothesis (namely $\theta_i=0$) is from a standard normal $\mathcal{N}(0, 1)$. We test two different models for $x_i$ under the alternative hypothesis (namely $\theta_i=1$) as follows.

Model 1: $x_i | \theta_i=1$ comes from a mixture of Gaussians

$$\frac{1}{3} \mathcal{N}(1, 1) + \frac{1}{3} \mathcal{N}(\mu, 1) + \frac{1}{3} \mathcal{N}(5, 1).$$  

(10)

In total, we test nine values for $\mu$, namely 1.4, 1.8, 2.2, 2.6, 3.0, 3.4, 3.8, 4.2 and 4.6. Different $\mu$ values yield different $f_1$ with different shapes.

Model 2: $x_i | \theta_i=1$ comes from a Gaussian $\mathcal{N}(\mu, 1)$ and $\mu$ has a prior of $\text{Gamma}(2.0, \beta)$ where $\beta$ is the scale parameter. We test six different values for $\beta$, namely 1.0, 1.2, 1.4, 1.6, 1.8 and 2.0. This model is designed to mimic the common situation in GWAS that common genetic variants have small effect sizes and rare genetic variants have large effect sizes (Manolio et al., 2009).

We compare three measures from these procedures. First, we check whether these procedures are valid, namely whether the FDR yielded from these procedures is controlled at the nominal level $\alpha$. The nominal FDR level $\alpha$ is 0.10, which is consistent with the multiple testing literature (Efron, 2010). Second, we compare the FNR yielded from these procedures. The third measure is the average number of true positives (ATP) of these procedures. Valid procedures with a lower FNR and a higher ATP are considered to be more efficient (or powerful). In the simulations, each experiment is replicated 500 times and the average results are reported.

Performance under chain structure: The performance of the five procedures under the chain dependence structure is shown in Figures 4 and 5, which correspond to Model 1 and Model 2, respectively. It is observed that all five procedures are valid. The parametric procedure (Liu et al., 2012) is conservative, which agrees with the observations in Figure 3(1d) of Liu et al. (2012). Our semiparametric
Multiple Testing under Dependence via Semiparametric Graphical Models

Figure 4. Performance of the procedures under Model 1 when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is chain.

Figure 5. Performance of the procedures under Model 2 when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is chain.

data-driven procedure, the BH procedure and the local FDR procedure are slightly conservative. The oracle procedure slightly outperforms the semiparametric data-driven procedure based the plots for FNR and ATP. These two completely dominate the three baselines, which indicates the benefit of leveraging dependence among the hypotheses via the semiparametric graphical model. We also observe that the advantage of the oracle procedure and our semiparametric data-driven procedure over the local FDR procedure is larger when $\phi = 0.8$ than when $\phi = 0.6$. The reason is that as $\phi$ decreases from 0.8 to 0.6, the dependence strength among the hypotheses decreases, and we benefit less from leveraging the dependence. When $\phi = 0.5$, the edge potentials in our graphical model are no longer informative, and the node potentials become the priors in the local FDR procedure, and our procedure exactly reduces to the local FDR procedure.

Performance under grid structure: The performance of the five procedures under the grid dependence structure is shown in Figures 6 and 7, which correspond to Model 1 and Model 2, respectively. All five procedures are valid. The parametric procedure is considerably conservative, which agrees with the observations in Figure 3(3d) of Liu et al. (2012). Again, our semiparametric data-driven procedure significantly outperforms the three baselines in all the configurations, demonstrating the benefit of leveraging dependence among the hypotheses via the semiparametric graphical model. The difference between our semiparametric data-driven procedure and the baselines is even larger compared with simulations under the chain structure. The reason is that in the grid structure, each hypothesis has more neighbors than in the chain structure, and we can benefit more from leveraging the dependence among the hypotheses.

Robustness of $\lambda$: In the previous simulations, $\lambda$ is fixed at 0.8. We test another two values for $\lambda$, namely 0.2 and 0.5, and repeat previous simulations. The performance of our semiparametric procedure under the chain dependence
structure and Model 1 with $\phi = 0.8$ is provided in Figure 8. Quite surprisingly, our data-driven semiparametric procedure is valid for the three values of $\lambda$ and is slightly conservative for most of the configurations. However, the FNR and ATP of our data-driven procedure for the three different values of $\lambda$ are almost the same. Therefore although our approach needs to pick a $\lambda$ parameter, its performance is robust for different choices of $\lambda$. The robustness of $\lambda$ was also observed in the work of Storey (2002). The sensitivity analysis of $\lambda$ in other configurations yield similar observations, and is given in Appendix 1 (in the supplementary materials).

**Efficiency of Ranking:** Although ranking the hypotheses by the probability that $H_0$ is false is a secondary goal in multiple testing, readers may wonder how well our semiparametric procedure performs in terms of ranking the hypotheses. For the oracle procedure, the parametric procedure (Liu et al., 2012) and our semiparametric procedure, we rank the hypotheses by the posterior probability that $H_0$ is false, namely $1 - \text{LIS}$. For BH, we use $1 - P$-value. For local FDR procedure, we use $1 - \lfloor df \rfloor$. Here we plot the ROC curves and PR curves yielded by the five procedures in Figure 9 for $\mu = 1.4$ and $\phi = 0.8$ in the chain structure under model 1. We observe that the oracle procedure produces the most efficient ranking, followed by the semiparametric procedure and the parametric procedure. The rankings yielded by local FDR and BH procedure are less effi-
cient. The ROC curves and PR curves of these procedures under other configurations show similar behavior, and are provided in Appendix 2 (in the supplementary materials).

Run Time: In the chain-structure simulations, it took our data-driven procedure about 10 hours to finish the 500 replications sequentially (for one $\mu$ value in (10)) on one 3GHz CPU. In the grid-structure simulations, it took our procedure around 30 hours to finish the 500 replications sequentially (for one $\mu$ value in (10)) on one 3GHz CPU.

6. Application

We apply our procedure to a real-world GWAS on breast cancer (Hunter et al., 2007) which involves 528,173 SNPs for 1,145 cases and 1,142 controls. In total, we test 528,173 hypotheses, and they are dependent because SNPs nearby tend to be highly correlated. We query the squared correlation coefficients ($r^2$ values) among the SNPs from HapMap (International HapMap Consortium, 2003), and build the dependence structure as follows. Each SNP becomes a node in the graph. For each SNP, we connect it with the SNP having the highest $r^2$ value with it. We further categorize the edges into a high correlation edge set $E_h$ ($r^2$ above 0.8), a medium correlation edge set $E_m$ ($r^2$ between 0.5 and 0.8) and a low correlation edge set $E_l$ ($r^2$ between 0.25 and 0.5). We have three parameters ($\phi_h$, $\phi_m$, and $\phi_l$) for the three sets of edges.

When we apply our procedure on the dataset, the individual test is a two-proportion $z$-test. We set $\lambda = 0.8$, and the value of $p_0$ is estimated to be 0.978, which means that about 2.2% of the SNPs are associated to breast cancer. The estimated $f_1$ in this study is plotted in Figure 1. The whole experiment takes around 30 hours on a single processor. Our procedure reports 20 SNPs with LIS value below 0.01. There are five clusters covering 18 of them. All 18 SNPs have very small $P$-values from the two-proportion $z$-test and locate near one another in the same cluster. The first cluster on Chr2, the cluster on Chr4, the cluster on Chr9 and the cluster on Chr10 are identified in the studies of Hunter et al. (2007) and Satrom et al. (2009). The second cluster on Chr2 is associated to a telomere and telomeres are known to be related to breast cancer (Svenson et al., 2008). We further use a second cohort to validate the 18 SNPs, and 16 of them show a moderate level of association on the second cohort. More details are provided in Appendix 3 (in the supplementary materials). We also would like to mention that there is some work on estimating less conservative significance thresholds for controlling family-wise error rate in GWAS (Salyakina et al., 2005; Han & Eskin, 2010).

7. Conclusion

We propose a novel semiparametric graphical model to leverage the dependence in multiple testing problems. Although our semiparametric approach seems incremental over previous fully parametric approach (Sun & Cai, 2009; Liu et al., 2012) from the viewpoint of graphical models, such a modification is nontrivial to the multiple testing area, for both a methodological reason and an application reason. From the methodological standpoint, our semiparametric approach naturally generalizes the local FDR procedure and connects with the BH procedure — we show that both the BH procedure and the local FDR procedure estimate their parameters in the same semiparametric way to avoid assumptions about $f_1$. The methodological unification demonstrates that such a modification is necessary for multiple testing. From the application aspect, our semiparametric approach no longer requires the investigators to know the parameterization of $f_1$, which is generally unknown in practical problems. Improper parameterization assumptions for $f_1$ can make the fully parametric approach either too liberal which makes the procedure invalid, or too conservative which makes the procedure lose power, as illustrated by both our simulations and previous work (Sun & Cai, 2009; Liu et al., 2012). Our semiparametric approach better controls FDR and is more powerful. For these reasons, we suggest that investigators choose the semiparametric approach for their large-scale multiple testing problems if (i) they speculate that there exists dependence among the hypotheses, and (ii) there is no suitable parametric distribution for $f_1$.

Multiple Testing under Dependence via Semiparametric Graphical Models
Appendix 1. Sensitivity Analysis of $\lambda$

We test three different values for $\lambda$, namely 0.2, 0.5 and 0.8, and repeat the simulations in the main text. In the main text, we only report the results for the chain dependence structure with $\phi = 0.8$ under Model 1 due to the limitation of space. In this appendix, we have the space to report all the configurations. Figure 1 is for the chain structure with $\phi = 0.8$ and $\phi = 0.6$ when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is chain and $f_1$ is from model 1.

Figure 1: Performance of our procedure when $\lambda$ is 0.2 (dotted lines), 0.5 (dashed lines) and 0.8 (solid lines) when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is chain and $f_1$ is from model 1.

Appendix 2. ROC/PR Curves for Other Configurations

In the main text, we only show the ROC curve and the PR curve for $\mu = 1.4$. Here we provide all the ROC curves and PR curves for the other eight values of $\mu$ in Figure 5 and Figure 6.

Appendix 3. Validation of the GWAS Findings on the Second Dataset

In the main text, we applied our procedure on a real-world GWAS on breast cancer and identified 18 SNPs which can be potentially associated with breast cancer. In addition to their association evidence in the literature, we further validate the 18 SNPs on a second cohort which include 162 breast cancer cases and 162 controls.
Figure 3: Performance of our procedure when $\lambda$ is 0.2 (dotted lines), 0.5 (dashed lines) and 0.8 (solid lines) when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is grid and $f_1$ is from model 1.

Figure 4: Performance of our procedure when $\lambda$ is 0.2 (dotted lines), 0.5 (dashed lines) and 0.8 (solid lines) when (1) $\phi = 0.8$ and (2) $\phi = 0.6$ in terms of (a) FDR (b) FNR and (c) ATP when the dependence structure is grid and $f_1$ is from model 2.

On the second cohort, we calculate the odds-ratio of the 18 SNPs, as listed in Table 1. It turns out that 16 of them show a moderate level of association. The five SNPs in the first cluster (on Chr2) have odds-ratio around 1.17-1.20. The four SNPs in the second cluster (on Chr2) have odds-ratio around 1.15-1.17. The two SNPs in the third cluster (on Chr4) have odds-ratio around 1.02. The four SNPs in the fourth cluster (on Chr9) have odds-ratio around 1.06-1.08. The three SNPs in the last cluster (on Chr10) have odds-ratio around 1.15-1.20.

1 The Modified PCD algorithm

The original PCD algorithm is for learning parameters in Markov random fields with observed data. It cannot be applied to our Markov-random-field-coupled mixture models (a.k.a. hidden Markov random fields) because \( \theta \) is hidden. Here we provide the modified PCD algorithm for learning parameters in the Markov random field part of our MRF-coupled mixture model. Essentially in the modified PCD algorithm, we need to calculate the probability \( \theta_i = 0 \) (namely the local FDR) from both the observed statistics and the generated observable particle statistics. Then we can update the parameters by matching the moments from them. The details are given in Algorithm 1. We call the modified PCD algorithm the \( PC_{Dh} \) algorithm.

The modified PCD algorithm accommodates the fact that in our semiparametric MRF-coupled mixture model, the \( f_1 \) is estimated nonparametrically. The pseudocode is also given the context of our graphical model in the simulations, namely there are two parameters to estimate, namely \( \phi \) and \( \pi \) which are in the pairwise edge potentials and the node potentials of the MRF on hidden vector \( \theta \).
Algorithm 1 $PCD_h$ algorithm for hidden MRFs

**Input:** observed data $\mathbf{x} = (x_1, ..., x_m)$, maximum iteration number $T$, the total number of hidden particle $N_h$, the total number of observable particles $N_o(= 20,000)$, function $f_0$ and the nonparametrically estimated $\hat{f}_1$, initial values for $\hat{\phi}^{(0)}$ and $\hat{\pi}^{(0)}$, learning rate $\eta$ which gradually decreases in iterations, the $n$ parameter in original PCD algorithm

**Output:** $\hat{\phi}$ and $\hat{\pi}$ from the last iteration

**Procedure:**

1. Initialize the observable particles: $Y_j = -10.0 + j \times 0.001$ for $j = 1, ..., 20,000$ ; // Uniformly distributed on the interval $[-10.0,10.0]$ which covers most of the mass of $f_0$ and $f_1$

2. Calculate $\text{lfdr}(Y_j) = \frac{f_0(Y_j)}{f_0(Y_j) + f_1(Y_j)}$ for $j = 1, ..., 20,000$. // Local FDR at these observable particles

3. Calculate $f_0(Y_j)$ and $\hat{f}_1(Y_j)$ for $j = 1, ..., 20,000$. // The weights of observable particles for $\theta = 0$ and $\theta = 1$ respectively

4. Calculate $E_0[\text{lfdr}] = \sum_{j=1}^{20,000} \text{lfdr}(Y_j) \times f_0(Y_j) \times 0.001$. // Expected local FDR for $\theta = 0$

5. Calculate $E_1[\text{lfdr}] = \sum_{j=1}^{20,000} \text{lfdr}(Y_j) \times \hat{f}_1(Y_j) \times 0.001$ // Expected local FDR for $\theta = 1$

6. Calculate $\text{lfdr}(x_k) = \frac{f_0(x_k)}{f_0(x_k) + f_1(x_k)}$ for $k = 1, ..., m$. // Local FDR at observed data

7. 

for $t = 1$ to $T$ do

7.1 For $k = 1, ..., N_h$: Advance particle $\theta^{(t)}_k$ according to $\hat{\phi}^{(t-1)}$ and $\hat{\pi}^{(t-1)}$ for $n$ MCMC steps.

7.2 For every edge $(i, j) \in \mathcal{E}$: Calculate edge moment from particle $\theta^{(t)}_k$ ($k = 1, ..., N_h$) and the edge moment from data. The moment of edge $(i, j)$ from particle $\theta^{(t)}_k$ is $\frac{Z_1}{Z_1 + Z_2}$ where

\[
Z_1 = E_{\theta^{(t)}_k}[\text{lfdr}]E_{\theta^{(t)}_k}[\text{lfdr}] + (1 - E_{\theta^{(t)}_k}[\text{lfdr}]) (1 - E_{\theta^{(t)}_k}[\text{lfdr}] ) ,
\]

\[
Z_2 = (1 - E_{\theta^{(t)}_k}[\text{lfdr}]) E_{\theta^{(t)}_k}[\text{lfdr}] + E_{\theta^{(t)}_k}[\text{lfdr}] (1 - E_{\theta^{(t)}_k}[\text{lfdr}]) .
\]

The moment of edge $(i, j)$ from the data $\mathbf{x}$ is $\frac{W_1}{W_1 + W_2}$ where

\[
W_1 = \text{lfdr}(x_i)\text{lfdr}(x_j) + (1 - \text{lfdr}(x_i)) (1 - \text{lfdr}(x_j)) ,
\]

\[
W_2 = (1 - \text{lfdr}(x_i))\text{lfdr}(x_j) + \text{lfdr}(x_i) (1 - \text{lfdr}(x_j)) .
\]

7.3 For every node $i \in \mathcal{V}$: Calculate node moment from particle $\theta^{(t)}_k$ ($k = 1, ..., N_h$) and node moment from data. The moment of node $i$ from particle $\theta^{(t)}_k$ is $E_{\theta^{(t)}_k}[\text{lfdr}]$. The moment of node $i$ from the data $\mathbf{x}$ is $\text{lfdr}(x_i)$.

We need to average over all the edges in $\mathcal{E}$. We also need to average over all the particles $\theta^{(t)}_k$ for $k = 1, ..., N_h$ when calculating moment from particles.

7.4 Update $\hat{\phi}$: $\hat{\phi}^{(t)} = \hat{\phi}^{(t-1)} + \eta \times \text{difference in edge moment between data and particles}$.

7.5 Update $\hat{\pi}$: $\hat{\pi}^{(t)} = \hat{\pi}^{(t-1)} + \eta \times \text{difference in node moment between data and particles}$.

7.6 If converge, then break.

end for
