GCVPACK - ROUTINES FOR GENERALIZED CROSS VALIDATION

Douglas M. Bates Mary J. Lindstrom Grace Wahba Brian S. Yandell

Department of Statistics University of Wisconsin–Madison

Key Words and Phrases: ill-posed problems; partial thin plate smoothing splines; penalized likelihood; semi-parametric models; ridge regression; thin plate smoothing splines; truncated singular value decomposition.

Abstract

A set of Fortran-77 subroutines to provide building blocks for Generalized Cross Validation calculations is presented. We outline applications in ridge regression, thin-plate smoothing splines to approximate smooth multivariate functions observed with noise and a new technique of using partial spline models. Timing tests and the structure of the main driver routines are also presented.

Purpose and Description

Purpose

These Fortran-77 subroutines provide building blocks for Generalized Cross-Validation (GCV) (Craven and Wahba, 1979) calculations in data analysis and data smoothing including ridge regression (Golub, Heath, and Wahba, 1979), thin plate smoothing splines (Wahba and Wendelberger, 1980), deconvolution (Wahba, 1982d), smoothing of generalized linear models (O'Sullivan, Yandell and Raynor (1986), Green (1984) and Green and Yandell (1985)), and ill-posed problems (Nychka et al., 1984, O'Sullivan and Wahba, 1985). We present some of the types of problems for which GCV is a useful method of choosing a smoothing or regularization parameter and we describe the structure of the subroutines.

Ridge Regression: A familiar example of a smoothing parameter is the ridge parameter λ in the ridge regression problem which we write as

$$\min_{\mathbf{y}} \quad \frac{1}{n} \|\mathbf{y} - \mathbf{X}\mathbf{y}\|^2 + \lambda \mathbf{y}^{\mathrm{T}}\mathbf{y}$$

where γ is a p-dimensional parameter vector, \mathbf{y} is an n-dimensional response vector and \mathbf{X} is an $n \times p$ design matrix.

For any positive λ , an optimal γ_{λ} can be easily calculated. Unfortunately, this leaves the question of which value of λ to use. Golub, Heath, and Wahba (1979) demonstrated that minimization of the GCV function $V(\lambda)$ is a powerful criterion for the choice of an optimal λ , where

$$V(\lambda) = \frac{(1/n) \| (\mathbf{I} - \mathbf{A}(\lambda)) \mathbf{y} \|^2}{[(1/n) \operatorname{tr}(\mathbf{I} - \mathbf{A}(\lambda))]^2}$$

and $A(\lambda)$ is the $n \times n$ "hat" matrix of the ridge regression

$$\mathbf{A}(\lambda) = \mathbf{X}(\mathbf{X}^{\mathrm{T}}\mathbf{X} + n\,\lambda\mathbf{I})^{-1}\mathbf{X}^{\mathrm{T}} .$$

At first glance, optimization of $V(\lambda)$ seems a formidable computational problem since each value of λ has its corresponding $\mathbf{A}(\lambda)$. However, Golub, Heath, and Wahba (1979) gave a method of expressing $V(\lambda)$ as an easily-calculated rational function based on the singular value decomposition (SVD) (Dongarra et al., 1979, chapter 10)

$$\mathbf{X} = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{T}}$$

where **U** is $n \times p$ with orthonormal columns, **V** is $p \times p$ and orthogonal, and **D** is $p \times p$ and diagonal with diagonal elements

$$d_1 \ge d_2 \ge \cdots \ge d_p \ge 0$$

which are the nonnegative square roots of the eigenvalues of $\mathbf{X}^T\mathbf{X}$. The "hat" matrix can then be written as

$$\mathbf{A}(\lambda) = \mathbf{U}\mathbf{D}^2(\mathbf{D}^2 + n\,\lambda\mathbf{I})^{-1}\mathbf{U}^{\mathrm{T}} ,$$

and using

$$\mathbf{z} = \mathbf{U}^{\mathrm{T}}\mathbf{y}$$

we can write

$$V(\lambda) = \frac{n \left[\|\mathbf{y}\|^{2} - \|\mathbf{z}\|^{2} + \sum_{j=1}^{p} \left[\frac{n\lambda}{d_{j}^{2} + n\lambda} \right]^{2} z_{j}^{2} \right]}{\left[n - p + \sum_{j=1}^{p} \frac{n\lambda}{d_{j}^{2} + n\lambda} \right]^{2}} . \quad (1.1)$$

Once the SVD of **X** is computed, it is trivial to evaluate $V(\lambda)$ for a wide range of values of λ and determine the optimum value of λ . Equation (1.1) indicates that, for most problems, $d_p^2 \le n \hat{\lambda} \le d_1^2$. After an optimal λ is chosen, the corresponding γ_{λ} is calculated as

$$\gamma_{\lambda} = \mathbf{V}(\mathbf{D}^2 + n\,\lambda\mathbf{I})^{-1}\mathbf{D}\mathbf{z} \quad . \tag{1.2}$$

Multivariate data smoothing with thin-plate splines: A more important application of GCV is determining smooth representations of an underlying multivariate function from which noisy data is observed. The ridge regression problem serves as an introduction to the idea of GCV and the computational steps for efficient evaluation of the GCV function but data smoothing using thin-plate smoothing splines (TPSS) is a much more common application of GCV. These methods extend the computational methods derived in Wahba and Wendelberger (1980), Wendelberger (1981), and Wahba (1984a).

For convenience we first describe the calculations for a two-dimensional "independent" variable \mathbf{x} but the software is designed for the general case. The data model for TPSS is

$$y_i = f(\mathbf{x}_i) + \varepsilon_i$$
, $i = 1, \ldots, n$,

where the (\mathbf{x}_i, y_i) , $i = 1, 2, \ldots, n$, are observed data, f is an unknown function which is assumed to be reasonably smooth, and the ε_i , $i = 1, 2, \ldots, n$, are independent, zero-mean random variables.

In general we will measure smoothness of f by the integral over the entire plane of the square of the partial derivatives of f of total order 2. That is,

$$J_2(f) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[\left[\frac{\partial^2 f}{\partial x_1^2} \right]^2 + 2 \left[\frac{\partial^2 f}{\partial x_1 \partial x_2} \right]^2 + \left[\frac{\partial^2 f}{\partial x_2^2} \right]^2 \right] dx_1 dx_2 .$$

To allow generalizations, the software uses a smoothness penalty defined by the partial derivatives of total order m as

$$J_m(f) = \int_{-\infty}^{\infty} \int_{i=0}^{\infty} \sum_{i=0}^{m} {m \choose i} \left[\frac{\partial^m f(x_1, x_2)}{\partial x_1^i \partial x_2^{m-i}} \right]^2 dx_1 dx_2 .$$

In d dimensions,

$$J_m(f) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \sum \frac{m!}{\alpha_1! \cdots \alpha_d!} \left[\frac{\partial^m f}{\partial x_1^{\alpha_1} \cdots \partial x_2^{\alpha_d}} \right]^2 dx_1 \cdots dx_d$$

with the sum within the integral over $\sum \alpha_i = m$. In general, one must have 2m - d > 0 with d the dimension of \mathbf{x} . Using this smoothness penalty, the TPSS estimate f_{λ} of f is the minimizer of

$$S_{\lambda}(f) = \frac{1}{n} \sum_{i=1}^{n} (y_i - f(\mathbf{x}_i))^2 + \lambda J_m(f) . \qquad (2.1)$$

From Duchon (1976), the minimizer f_{λ} of (2.1) can be represented as

$$f_{\lambda}(\mathbf{x}) = \sum_{i=1}^{t} \beta_i \phi_i(\mathbf{x}) + \sum_{i=1}^{n} \delta_i E_m(\mathbf{x} - \mathbf{x}_i)$$
 (2.2)

where

$$E_m(\mathbf{t}) = (-1)^m 2^{1-2m} \pi^{-1} ((m-1)!)^{-2} \| \mathbf{t} \|^{(2m-2)} \ln(\| \mathbf{t} \|)$$

and t is the dimension of the space of polynomials on two variables of total order at most m-1,

$$t = \begin{bmatrix} m+1 \\ 2 \end{bmatrix} .$$

A basis for this space is

$$\phi_1(\mathbf{x}) = 1$$

$$\phi_2(\mathbf{x}) = x_1$$

$$\phi_3(\mathbf{x}) = x_2$$

$$\phi_4(\mathbf{x}) = x_1^2$$

$$\phi_5(\mathbf{x}) = x_1 x_2$$

$$\phi_t(\mathbf{x}) = x_2^{m-1} \quad .$$

The general definition of E_m , which depends on the dimension, d, of the independent variables x is

$$E_{m}(\mathbf{t}) = \begin{cases} a_{m d} \|\mathbf{t}\|^{(2m-d)} \ln(\|\mathbf{t}\|), & d \text{ even} \\ a_{m d} \|\mathbf{t}\|^{(2m-d)}, & d \text{ odd} \end{cases},$$
 (2.3)

with

$$a_{md} = \begin{cases} (-1)^{1+m+d/2} 2^{1-2m} \pi^{-d/2} ((m-1)! (m-d/2)!)^{-1} & , d \text{ even} \\ \Gamma(\frac{d}{2} - m) 2^{-2m} \pi^{-d/2} ((m-1)!)^{-1} & , d \text{ odd} \end{cases}.$$

The dimension, t, of the polynomial space is given in general by

$$t = \begin{bmatrix} m+d-1 \\ d \end{bmatrix} .$$

A property of the TPSS representation is that both the function f_{λ} evaluated at the data points and the smoothing penalty J_m can be expressed using the $n \times n$ matrix K with entries

$$\{\mathbf{K}\}_{ij} = E_m(\mathbf{x}_i - \mathbf{x}_j) . \tag{2.4}$$

The function f_{λ} also requires the $n \times t$ matrix **T** with entries

$$\{\mathbf{T}\}_{ij} = \phi_j(\mathbf{x}_i) .$$

The matrix T having full column rank guarantees a unique minimizer of (2.1). Duchon (1976) showed that δ in (2.2) must satisfy

$$\mathbf{T}^{\mathrm{T}}\mathbf{\delta} = \mathbf{0} \quad . \tag{2.5}$$

Then β_{λ} and δ_{λ} are the minimizers of (2.1), which can be written as

$$S_{\lambda}(\beta, \delta) = \frac{1}{n} \| \mathbf{y} - \mathbf{T}\beta - \mathbf{K}\delta \|^{2} + \lambda \delta^{T} \mathbf{K}\delta$$
.

Note that the restriction in (2.5) is important, as K will generally have negative eigenvalues, but for any vectors δ satisfying (2.5) it can be shown that

$$\delta^{\mathrm{T}}\mathbf{K}\delta \geq 0$$
.

Our objective is to reduce the calculation of the parameters β_{λ} and δ_{λ} , the "hat" matrix $\mathbf{A}(\lambda)$, and the GCV function $V(\lambda)$ to a simplified form as was done for the ridge regression case.

No replicates case: When there are no replicates in the x's, we proceed by taking a QR decomposition (Dongarra et al., 1979, chapter 9) of T as

$$\boldsymbol{T} = \boldsymbol{F}\boldsymbol{G} = [\boldsymbol{F}_1 {:} \boldsymbol{F}_2] \begin{bmatrix} \boldsymbol{G}_1 \\ \boldsymbol{0} \end{bmatrix} = \boldsymbol{F}_1 \boldsymbol{G}_1$$

where \mathbf{F} is $n \times n$ and orthogonal while \mathbf{G} is $n \times t$ and zero below the main diagonal. \mathbf{F}_1 is the first t columns of \mathbf{F} and \mathbf{F}_2 is the trailing n-t columns while \mathbf{G}_1 is the first t rows of \mathbf{G} . The columns of \mathbf{F}_2 provide a basis for the δ which satisfy

$$\mathbf{T}^{\mathrm{T}}\mathbf{\delta} = \mathbf{0}$$

so we can set

$$\delta = \mathbf{F}_2 \zeta$$

where ζ has dimension n-t. Using

$$\mathbf{w}_1 = \mathbf{F}_1^{\mathrm{T}} \mathbf{y}$$

$$\mathbf{w}_2 = \mathbf{F}_2^{\mathrm{T}} \mathbf{y}$$

the objective function of the optimization becomes

$$S_{\lambda}(\boldsymbol{\beta}, \boldsymbol{\delta}) = \frac{1}{n} \| \mathbf{y} - \mathbf{T}\boldsymbol{\beta} - \mathbf{K}\boldsymbol{\delta} \|^{2} + \lambda \, \boldsymbol{\delta}^{T}\mathbf{K}\boldsymbol{\delta}$$

$$= \frac{1}{n} \| \mathbf{F}^{T}(\mathbf{y} - \mathbf{T}\boldsymbol{\beta} - \mathbf{K}\boldsymbol{\delta}) \|^{2} + \lambda \, \boldsymbol{\delta}^{T}\mathbf{K}\boldsymbol{\delta}$$

$$= \frac{1}{n} \| \mathbf{w}_{1} - \mathbf{G}_{1}\boldsymbol{\beta} - \mathbf{F}_{1}^{T}\mathbf{K}\mathbf{F}_{2}\boldsymbol{\zeta} \|^{2}$$

$$+ \frac{1}{n} \| \mathbf{w}_{2} - \mathbf{F}_{2}^{T}\mathbf{K}\mathbf{F}_{2}\boldsymbol{\zeta} \|^{2} + \lambda \, \boldsymbol{\zeta}^{T}\mathbf{F}_{2}^{T}\mathbf{K}\mathbf{F}_{2}\boldsymbol{\zeta} .$$
(2.6)

Assuming G_1 is non-singular (that is, the points \mathbf{x}_i , $i = 1, \ldots, n$, are adequately dispersed so that the columns of \mathbf{T} are linearly independent) the first term in (2.6) can be made zero by solving

$$\mathbf{G}_1 \boldsymbol{\beta}_{\lambda} = \mathbf{w}_1 - \mathbf{F}_1^{\mathrm{T}} \mathbf{K} \mathbf{F}_2 \boldsymbol{\zeta}_{\lambda}$$
$$= \mathbf{w}_1 - \mathbf{F}_1^{\mathrm{T}} \mathbf{K} \boldsymbol{\delta}_{\lambda}$$

for β_{λ} . In practice we check the condition of \mathbf{G}_1 and return an error condition if it is computationally singular, indicating that the columns of \mathbf{T} are strongly correlated. This condition is equivalent to the computational singularity of the problem of least squares regression of the data onto the span $\{\phi_j\}$. Singularity will rarely occur since the column dimension of \mathbf{T} is small.

We can now reduce the problem to a form like ridge regression by using the fact that $\mathbf{F}_2^T\mathbf{K}\mathbf{F}_2$ is positive definite to form the Cholesky decomposition (Dongarra et al., 1979, chapter 8)

$$\mathbf{F}_2^{\mathrm{T}}\mathbf{K}\mathbf{F}_2 = \mathbf{L}^{\mathrm{T}}\mathbf{L}$$

where **L** is $(n-t) \times (n-t)$ and upper triangular. In practice we use a pivoted Cholesky decomposition so we can check the conditioning of $\mathbf{F}_2^T \mathbf{K} \mathbf{F}_2$. If this matrix is computationally singular, which can occur if $\|\mathbf{x}_i - \mathbf{x}_j\|$ is very small but non-zero for some $i \neq j$, we return an error condition. A near-singular $\mathbf{F}_2^T \mathbf{K} \mathbf{F}_2$ is usually avoided since, in checking for replicates, we declare \mathbf{x}_i and \mathbf{x}_j to be replicates if the distance between them is very small. See Appendix 1 for more information on the detection of replicates and the computational singularity of **L**.

After ensuring that L is non-singular, we define

$$\gamma = L\zeta$$

and the last two terms of $S_{\lambda}(\beta,\delta)$ in (2.6) can be written as

$$\frac{1}{n} \|\mathbf{w}_2 - \mathbf{L}^{\mathrm{T}} \boldsymbol{\gamma} \|^2 + \lambda \boldsymbol{\gamma}^{\mathrm{T}} \boldsymbol{\gamma}.$$

This has the same form as the ridge regression problem with solution

$$\gamma_{\lambda} = (\mathbf{L}\mathbf{L}^{\mathrm{T}} + n\,\lambda\mathbf{I})^{-1}\mathbf{L}\mathbf{w}_{2}$$
.

We take a SVD of LT as

$$\mathbf{L}^{\mathrm{T}} = \mathbf{U} \mathbf{D} \mathbf{V}^{\mathrm{T}}$$

and write the estimate as

$$\gamma_{\lambda} = \mathbf{V}(\mathbf{D}^2 + n \lambda \mathbf{I})^{-1} \mathbf{D} \mathbf{U}^{\mathrm{T}} \mathbf{w}_2$$

and the "hat" matrix as

$$\mathbf{A}(\lambda) = \mathbf{F}_1 \mathbf{F}_1^{\mathrm{T}} + \mathbf{F}_2 \mathbf{U} \mathbf{D}^2 (\mathbf{D}^2 + n\lambda \mathbf{I})^{-1} \mathbf{U}^{\mathrm{T}} \mathbf{F}_2^{\mathrm{T}}$$

$$= \mathbf{F} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{U} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{D}^2 (\mathbf{D}^2 + n\lambda \mathbf{I})^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{U}^{\mathrm{T}} \end{bmatrix} \mathbf{F}^{\mathrm{T}} . \tag{2.7}$$

As in the ridge regression case, we use

$$\mathbf{z} = \mathbf{U}^{\mathrm{T}} \mathbf{w}_2$$

to write

$$V(\lambda) = \frac{n \sum_{j=1}^{n-t} \left[\frac{n \lambda}{d_j^2 + n \lambda} \right]^2 z_j^2}{\left[\sum_{j=1}^{n-t} \frac{n \lambda}{d_j^2 + n \lambda} \right]^2} . \tag{2.8}$$

The actual calculation of the parameter δ_{λ} corresponding to the E_m 's is performed as

$$\delta_{\lambda} = \mathbf{F}_{2}\mathbf{U}(\mathbf{D}^{2} + n\lambda\mathbf{I})^{-1}\mathbf{z}$$

$$= \mathbf{F}_{2}\mathbf{U}(\mathbf{D}^{2} + n\lambda\mathbf{I})^{-1}\mathbf{U}^{\mathrm{T}}\mathbf{F}_{2}^{\mathrm{T}}\mathbf{y} . \tag{2.9}$$

Replicated x values: Replicates of x values introduce some minor complications since we must define only one δ_i corresponding to each unique x position. The best way to handle this is to pre-process the data by sorting the x values to determine the unique x values and the number of replicates of each value. Let k be the number of unique x values. We can express the objective function optimized by δ_{λ} and β_{λ} as

$$S_{\lambda}(\beta,\delta) = \frac{1}{n} \|\mathbf{y} - \mathbf{T}\boldsymbol{\beta} - \mathbf{K}\boldsymbol{\delta}\|^{2} + \lambda \boldsymbol{\delta}^{\mathrm{T}}\mathbf{K}_{U}\boldsymbol{\delta}$$
 (3.1)

subject to the condition

$$\mathbf{T}_U^{\mathrm{T}} \mathbf{\delta} = \mathbf{0}$$

where **T** and **K** are of size $n \times t$ and $n \times k$ respectively, while **T**_U and **K**_U are of size $k \times t$ and $k \times k$ respectively. These matrices are related by

$$\mathbf{T} = \mathbf{M}\mathbf{T}_U$$
$$\mathbf{K} = \mathbf{M}\mathbf{K}_U$$

where **M** is an $n \times k$ indicator matrix (all its entries are ones or zeros and there is only a single one in each row) which, for each row, indicates the unique **x** that corresponds to that observation.

If we take a QR decomposition of M as

$$\mathbf{M} = \mathbf{BC} = [\mathbf{B}_1 : \mathbf{B}_2] \begin{bmatrix} \mathbf{C}_1 \\ \mathbf{0} \end{bmatrix} = \mathbf{B}_1 \mathbf{C}_1$$

and pre-multiply all the vectors in the first term of (3.1) by \mathbf{B} , (3.1) divides into

$$S_{\lambda}(\boldsymbol{\beta}, \boldsymbol{\delta}) = \frac{1}{n} \| \mathbf{B}_{2}^{\mathsf{T}} \mathbf{y} \|^{2} + \frac{1}{n} \| \mathbf{B}_{1}^{\mathsf{T}} \mathbf{y} - \mathbf{C}_{1} \mathbf{T}_{U} \boldsymbol{\beta} - \mathbf{C}_{1} \mathbf{K}_{U} \boldsymbol{\delta} \|^{2} + \lambda \boldsymbol{\delta}^{\mathsf{T}} \mathbf{K}_{U} \boldsymbol{\delta} .$$

$$(3.2)$$

In practice, it is not necessary to explicitly form \mathbf{M} and take its QR decomposition since \mathbf{C}_1 is diagonal with c_{ii} being the square root of the number of replicates of the *i*'th unique \mathbf{x} . The elements of the vector $\mathbf{C}_1^{-1}\mathbf{B}_1^T\mathbf{y}$ are the means of the *y*'s at the corresponding unique \mathbf{x} 's. Further, $\|\mathbf{B}_2^T\mathbf{y}\|^2$ is the sum of squares due to replication.

With this information available we can write

$$\omega = C_1^{-T} \delta$$

to produce

$$S_{\lambda}(\boldsymbol{\beta}, \boldsymbol{\omega}) = \frac{1}{n} \| \mathbf{B}_{2}^{\mathrm{T}} \mathbf{y} \|^{2} + \frac{1}{n} \| \mathbf{B}_{1}^{\mathrm{T}} \mathbf{y} - \mathbf{C}_{1} \mathbf{T}_{U} \boldsymbol{\beta} - \mathbf{C}_{1} \mathbf{K}_{U} \mathbf{C}_{1}^{\mathrm{T}} \boldsymbol{\omega} \|^{2}$$
$$+ \lambda \boldsymbol{\omega}^{\mathrm{T}} \mathbf{C}_{1} \mathbf{K}_{U} \mathbf{C}_{1}^{\mathrm{T}} \boldsymbol{\omega}$$

and proceed as in the case with no replications using $\mathbf{C}_1\mathbf{T}_U$ in place of \mathbf{T} , and $\mathbf{C}_1\mathbf{K}_U\mathbf{C}_1^T$ in place of \mathbf{K} . That is, take a QR decomposition

$$\mathbf{C}_1\mathbf{T}_U = \mathbf{F}\mathbf{G} = [\mathbf{F}_1:\mathbf{F}_2] \begin{bmatrix} \mathbf{G}_1 \\ \mathbf{0} \end{bmatrix} = \mathbf{F}_1\mathbf{G}_1$$

and form $\mathbf{F}_{2}^{T}\mathbf{C}_{1}\mathbf{K}_{U}\mathbf{C}_{1}^{T}\mathbf{F}_{2}$ which then determines the Cholesky decomposition

$$\mathbf{F}_{2}^{\mathrm{T}}\mathbf{C}_{1}\mathbf{K}_{U}\mathbf{C}_{1}^{\mathrm{T}}\mathbf{F}_{2} = \mathbf{L}^{\mathrm{T}}\mathbf{L}$$
.

A SVD of L^{T} as

$$\mathbf{L}^{\mathrm{T}} = \mathbf{U} \mathbf{D} \mathbf{V}^{\mathrm{T}}$$

and the product

$$\mathbf{w}_2 = \mathbf{F}_2^{\mathrm{T}} \mathbf{B}_1^{\mathrm{T}} \mathbf{y}$$

allows us to write

$$V(\lambda) = \frac{n \left[\| \mathbf{B}_{2}^{\mathrm{T}} \mathbf{y} \|^{2} + \sum_{j=1}^{k-t} \left[\frac{n \lambda}{d_{j}^{2} + n \lambda} \right]^{2} z_{j}^{2} \right]}{\left[n - k + \sum_{j=1}^{k-t} \frac{n \lambda}{d_{j}^{2} + n \lambda} \right]^{2}}.$$

Given the value of $\hat{\lambda}$, the calculation of δ_{λ} and β_{λ} follow as in the no-replicates case. That is,

$$\delta_{\lambda} = \mathbf{C}_{1}^{\mathrm{T}} \mathbf{F}_{2} \mathbf{U} (\mathbf{D}^{2} + n \lambda \mathbf{I})^{-1} \mathbf{U}^{\mathrm{T}} \mathbf{F}_{2}^{\mathrm{T}} \mathbf{B}_{1}^{\mathrm{T}} \mathbf{y}$$

and β_{λ} is the solution of

$$\mathbf{G}_1 \boldsymbol{\beta}_{\lambda} = \mathbf{F}_1^{\mathrm{T}} (\mathbf{B}_1^{\mathrm{T}} \mathbf{y} - \mathbf{C}_1 \mathbf{K}_U \boldsymbol{\delta}_{\lambda}) .$$

Partial spline models: These are an extension to the thinplate smoothing spline model in which some of the coordinates of x, the "covariates", do not enter into the thin-plate spline. See Wahba (1984b, 1985) and Shiau, Wahba, and Johnson (1985). The model is

$$y_i = f(\mathbf{x}_i) + \sum_{j=1}^{c} \alpha_j \psi_j(\mathbf{x}_i, \mathbf{s}_i) + \varepsilon_i$$
 (4.1)

in which \mathbf{s}_i are the "covariates" and $\{\psi_j\}$ are c given functions. For convenience, we will consider these variables as forming another matrix \mathbf{S} of size $n \times c$. The partial spline estimates of f and α are the minimizers of

$$S_{\lambda}(\alpha,\beta,\delta) = \frac{1}{n} \sum_{i=1}^{n} \left[y_i - f(\mathbf{x}_i) - \sum_{j=1}^{c} \alpha_j \psi_j(\mathbf{x}_i,\mathbf{s}_i) \right]^2 + \lambda J_m(f) ,$$

and it is known that the minimizing f_{λ} has a representation of the form (2.2). Let **S** be the $n \times c$ matrix with ij'th entry $\psi_j(\mathbf{x}_i, \mathbf{s}_i)$. The matrix [**T**:**S**] must be of full column rank. The objective function for a fixed λ becomes

$$S_{\lambda}(\alpha,\beta,\delta) = \frac{1}{n} \|\mathbf{y} - \mathbf{S}\alpha - \mathbf{T}\beta - \mathbf{K}\delta\|^2 + \lambda \delta^{\mathrm{T}}\mathbf{K}\delta$$
.

When determining replicates, we only consider the d variables which determine the spline. When there are no replicates, we proceed as in the basic TPSS case except that we take the initial QR decomposition as

$$[T:S] = FG = [F_1:F_2] \begin{bmatrix} G_1 \\ 0 \end{bmatrix} = F_1G_1$$

so $V(\lambda)$ is calculated as in (2.8) with all summations running to n-t-c. That is, after the Cholesky decomposition of $\mathbf{F}_2^{\mathrm{T}}\mathbf{K}\mathbf{F}_2$ and the SVD of the transpose of the Cholesky factor, we have

$$V(\lambda) = \frac{n \sum_{j=1}^{n-t-c} \left[\frac{n\lambda}{d_j^2 + n\lambda} \right]^2 z_j^2}{\left[\sum_{j=1}^{n-t-c} \frac{n\lambda}{d_j^2 + n\lambda} \right]^2}.$$

The calculation of ζ_{λ} and δ_{λ} proceeds as in the basic TPSS case. With these available, we solve for α_{λ} and β_{λ} simultaneously. In other words, we have simply replaced $T\beta$ in (2.6) by

$$[T:S]$$
 $\begin{bmatrix} \beta \\ \alpha \end{bmatrix}$.

It can be shown that the implied constraint $S^T\delta = 0$ does not change the solution.

When we have covariates as well as some replications in the d coordinates of the \mathbf{x} 's, we have to distinguish between those columns of \mathbf{S} which follow the replication pattern of the \mathbf{x} 's and those which do not. If all the columns of \mathbf{S} follow the replication pattern, we have an indicator matrix \mathbf{M} for which

$$T = MT_U$$
 $K = MK_U$
 $S = MS_U$

Taking the QR decomposition of **M** as $\mathbf{M} = \mathbf{BC}$, we then take a QR decomposition of $\mathbf{C}_1[\mathbf{T}_U:\mathbf{S}_U]$ and proceed as above.

If there are columns of **S** which do not follow the replication pattern of the design, we need a more general approach. The covariate matrix is divided into $S = [S_1:S_2]$ in which the columns of S_1 have the same replication structure as the design points \mathbf{x}_i , $i = 1, \dots, n$. We have an indicator matrix **M** for which

$$[\mathbf{T}:\mathbf{S}_1:\mathbf{K}] = \mathbf{M}[\mathbf{T}_U:\mathbf{S}_{1U}:\mathbf{K}_U] ,$$

and a QR decomposition of $\mathbf{M} = \mathbf{BC}$ as above. However, we cannot easily reduce the objective function to a form such as (3.2) by premultiplying by \mathbf{B} , as $\mathbf{B}_2^T \mathbf{S}_2$ is not annihilated. Instead we choose to take a QR decomposition of

$$\mathbf{C}_1[\mathbf{T}_U:\mathbf{S}_{1U}] = \mathbf{F}\mathbf{G} = [\mathbf{F}_1:\mathbf{F}_2] \begin{bmatrix} \mathbf{G}_1 \\ \mathbf{0} \end{bmatrix} = \mathbf{F}_1\mathbf{G}_1$$

which is used to reduce the parameter vector and penalty matrix. We proceed as in the case of a general design matrix with a semi-norm penalty as described in the next section by creating the parameter vector

$$\theta = \begin{bmatrix} \beta \\ \alpha \\ \zeta \end{bmatrix} \text{, with } \delta = \mathbf{C}_1^T \mathbf{F}_2 \zeta \text{,}$$

and the design matrix

$$\mathbf{X} = [\mathbf{T}: \mathbf{S}_1: \mathbf{S}_2: \mathbf{K} \mathbf{C}_1^{\mathrm{T}} \mathbf{F}_2] .$$

The penalty becomes $\theta^T \Sigma \theta$, with

$$\Sigma = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{F}_2^{\mathrm{T}} \mathbf{C}_1 \mathbf{K}_U \mathbf{C}_1^{\mathrm{T}} \mathbf{F}_2 \end{bmatrix} .$$

Partial spline models with nodes at selected points, which may not actually correspond to data points, are discussed in Appendix 2.

General design matrix with a semi-norm penalty: The ridge regression case and the TPSS cases which we have considered both have some special structure. In the ridge regression case, the design matrix, \mathbf{X} , is general but the penalty term, $\mathbf{\gamma}^T \mathbf{\gamma}$, has a special form so we can streamline the calculations. In the TPSS cases, the penalty term, $\mathbf{\delta}^T \mathbf{K} \mathbf{\delta}$ subject to $\mathbf{T}^T \mathbf{\delta} = \mathbf{0}$, is more general but the design matrix, $[\mathbf{T}:\mathbf{K}]$ is related to the penalty so, again, we can exploit this special structure to provide faster algorithms. Even in the case with both a general design and a general penalty, though, we can still form efficient computational methods for GCV.

The most general GCV calculation we consider is the penalized least squares problem with an objective function

$$S_{\lambda}(\theta) = \frac{1}{n} \| \mathbf{y} - \mathbf{X}\theta \|^{2} + \lambda \theta^{T} \Sigma \theta$$
 (5.1)

where θ is a p-dimensional parameter vector, \mathbf{y} is an n-dimensional response vector, \mathbf{X} is an $n \times p$ design matrix, and Σ is a $p \times p$ positive semi-definite symmetric matrix defining the smoothness penalty. Note that partial splines can be written in this form as a special case.

A partial spline model with discontinuities in the $\{\psi_j\}$ of (4.1) which fits in the context of (5.1) is described in Shiau, Wahba, and Johnson (1985). Other special cases included splines and vector splines on the sphere (Wahba (1981), Wahba (1982a, 1982b, 1982c)) and remote sensing problems (Wahba (1980a)). Appendix 2 presents some examples and the algebra needed for a partial spline model with basis functions.

The minimization of (5.1) can also be used as a step in the iterative solution of penalized GLIM models (O'Sullivan (1983), O'Sullivan, Yandell and Raynor (1986)), nonlinear regularization (O'Sullivan (1983) and O'Sullivan and Wahba (1985)) and iteratively reweighted least squares (Green (1984), Green (1985) and Green and Yandell (1985)).

We can find the GCV estimate of λ in the general case by using a series of matrix decompositions to reduce (5.1) to the form of the ridge regression calculation as was done in the TPSS case. First we must isolate the null-space of the semi-norm defined by Σ . That is, we must describe the set of θ 's for which

$$\boldsymbol{\theta}^{\mathrm{T}} \boldsymbol{\Sigma} \, \boldsymbol{\theta} = \boldsymbol{0}$$
.

We assume the dimension, h, of this space is known and take a pivoted Cholesky decomposition (Dongarra et al., 1979, chapter 8)

$$\mathbf{E}^{\mathrm{T}} \mathbf{\Sigma} \mathbf{E} = \mathbf{L}^{\mathrm{T}} \mathbf{L}$$

where **E** is a $p \times p$ permutation matrix and **L** is $(p-h) \times p$ with zeros below the main diagonal. The conditioning of **L** is evaluated to ensure that **L** actually has computational rank p-h. If **L** is rank deficient, we increase h until the resulting $(p-h) \times p$ matrix **L** is of full row rank and return a non-fatal error code. If the user's value of h was too large, we return a fatal error code as this indicates that the null space of Σ is smaller than expected. As described in Appendix 1, the technique of increasing h until **L** is of full row rank is incompatible with the partial spline code as written here.

A QR decomposition of LT as

$$\mathbf{L}^{\mathrm{T}} = \mathbf{Q}\mathbf{R} = [\mathbf{Q}_1:\mathbf{Q}_2] \begin{bmatrix} \mathbf{R}_1 \\ \mathbf{0} \end{bmatrix} = \mathbf{Q}_1\mathbf{R}_1$$

provides the $h \times p$ matrix \mathbf{Q}_2 which is an orthogonal basis for the null space of the semi-norm defined by Σ . We can now transform to parameters γ and β of dimension p-h and h, respectively, as

$$\begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\beta} \end{bmatrix} = \begin{bmatrix} \boldsymbol{R}_1^T & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I} \end{bmatrix} \boldsymbol{Q}^T \boldsymbol{E}^T \boldsymbol{\theta}$$

where β lies in the null space and $S_{\lambda}(\theta)$ from (5.1) can be written

$$S_{\lambda}(\boldsymbol{\beta}, \boldsymbol{\gamma}) = \frac{1}{n} \| \mathbf{y} - \mathbf{X} \mathbf{E} \mathbf{Q} \begin{bmatrix} \mathbf{R}_{1}^{-T} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\beta} \end{bmatrix} \|^{2} + \lambda \boldsymbol{\gamma}^{T} \boldsymbol{\gamma}$$
$$= \frac{1}{n} \| \mathbf{y} - \mathbf{Z} \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\beta} \end{bmatrix} \|^{2} + \lambda \boldsymbol{\gamma}^{T} \boldsymbol{\gamma}$$

with

$$\boldsymbol{Z} = [\boldsymbol{Z}_1 : \boldsymbol{Z}_2] = \boldsymbol{X} \boldsymbol{E} \boldsymbol{Q} \begin{bmatrix} \boldsymbol{R}_1^{-T} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I} \end{bmatrix} .$$

This provides the desired form of the penalty term. We must now divide the least squares term into a part that can be made zero by an appropriate choice of β and a part that depends only on γ . Another QR decomposition, this time as

$$\mathbf{Z}_2 = \mathbf{FG} = [\mathbf{F}_1 : \mathbf{F}_2] \begin{bmatrix} \mathbf{G}_1 \\ \mathbf{0} \end{bmatrix}$$

is used to form

$$S_{\lambda}(\boldsymbol{\beta}, \boldsymbol{\gamma}) = \frac{1}{n} \| \mathbf{w}_{1} - \mathbf{G}_{1}\boldsymbol{\beta} - \mathbf{J}_{1}\boldsymbol{\gamma} \|^{2} + \frac{1}{n} \| \mathbf{w}_{2} - \mathbf{J}_{2}\boldsymbol{\gamma} \|^{2} + \lambda \boldsymbol{\gamma}^{T}\boldsymbol{\gamma}$$
(5.2)

where

$$\mathbf{w} = \begin{bmatrix} \mathbf{w}_1 \\ \mathbf{w}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{F}_1^{\mathrm{T}} \\ \mathbf{F}_2^{\mathrm{T}} \end{bmatrix} \mathbf{y} = \mathbf{F}^{\mathrm{T}} \mathbf{y}$$

and

$$\boldsymbol{J} = \begin{bmatrix} \boldsymbol{J}_1 \\ \boldsymbol{J}_2 \end{bmatrix} = \begin{bmatrix} \boldsymbol{F}_1^T \\ \boldsymbol{F}_2^T \end{bmatrix} \boldsymbol{Z}_1 = \boldsymbol{F}^T \boldsymbol{Z}_1 \ .$$

After checking that G_1 is non-singular, the first term in (5.2) can be made zero for any value of γ by solving

$$\mathbf{G}_1 \boldsymbol{\beta} = \mathbf{w}_1 - \mathbf{J}_1 \boldsymbol{\gamma} \tag{5.3}$$

for β . This reduces the general penalized least squares to the same form as the ridge regression. A singular value decomposition

$$\mathbf{J}_2 = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{T}} \tag{5.4}$$

produces the representation of the "hat" matrix as

$$\mathbf{A}(\lambda) = \mathbf{F} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{U} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{D}^2 (\mathbf{D}^2 + n \lambda \mathbf{I})^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{U}^T \end{bmatrix} \mathbf{F}^T .$$

The matrix **D** is $a \times a$, with a = min(n,p) - h, and the matrices **U** and **V** are rectangular of sizes $(n-h) \times a$ and $(p-h) \times a$, respectively. Again, using

$$\mathbf{z} = \mathbf{U}^{\mathrm{T}}\mathbf{w}_{2} \tag{5.5}$$

the GCV function can be expressed as

$$V(\lambda) = \frac{n \left[\|\mathbf{w}_{2}\|^{2} - \|\mathbf{z}\|^{2} + \sum_{j=1}^{a} \left[\frac{n\lambda}{d_{j}^{2} + n\lambda} \right]^{2} z_{j}^{2} \right]}{\left[n - p + \sum_{j=1}^{a} \frac{n\lambda}{d_{j}^{2} + n\lambda} \right]^{2}} . (5.6)$$

and the parameters vectors γ_{λ} , β_{λ} , and θ_{λ} are determined in the usual way given $\hat{\lambda}$, with (5.3) and

$$\gamma_{\lambda} = \mathbf{V} (\mathbf{D}^2 + n \, \lambda \mathbf{I})^{-1} \mathbf{D} \mathbf{U}^T \mathbf{w}_2 \ ,$$

yielding

$$\theta_{\lambda} = \mathbf{E} \mathbf{Q} \begin{bmatrix} \mathbf{R}_{1}^{-T} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \gamma_{\lambda} \\ \beta_{\lambda} \end{bmatrix} \ .$$

The biggest computational bottleneck is the SVD of J_2 when n and p are large, particularly since J_2 is often ill-conditioned. We can accelerate the SVD calculation by

using a truncated version of the singular value decomposition (Bates and Wahba, 1982). Notice that, in (5.6) and the solution of γ_{λ} , values of d_j such that

$$d_j^2 \ll n \lambda$$

can be set to zero without significantly changing the results. Starting with a tolerance $\tau \rho$, usually a small multiple (τ) of the relative machine precision (ρ) , the truncated SVD algorithm finds a matrix $\tilde{\mathbf{J}}_2$ which has $a^* \leq a$ positive singular values and satisfies

$$\frac{\|\mathbf{\tilde{J}}_2 - \mathbf{J}_2\|_F^2}{\|\mathbf{J}_2\|_F^2} < \tau \rho ,$$

in which $\| \bullet \|_F$ is the Frobenius norm. For details of the truncated SVD algorithm, see Appendix 3. We replace J_2 by \tilde{J}_2 in (5.4), thereby reducing the effective number of parameters to a^* . With the truncation we only calculate an $(n-h)\times a^*$ matrix U and a $(p-h)\times a^*$ matrix V so the vector \mathbf{z} defined in (5.5) will be a^* -dimensional, with a replaced by a^* . When J_2 is ill-conditioned, we get a^* considerably less than a and, since the calculation of the SVD is of order $O(na^2)$, this can create substantial savings in computing time. However, V is sensitive to τ for small λ . To check on the effect of the truncation on the value of $V(\lambda)$ and hence the calculation of $\hat{\lambda}$ we return the diagnostic quantity

$$n\hat{\lambda}/(n\hat{\lambda} + \|\tilde{\mathbf{J}}_2 - \mathbf{J}_2\|_F^2)$$
 (5.7)

This is a lower bound on each of the quantities $n\hat{\lambda}/(d_j^2 + n\hat{\lambda})$ in (5.6) which are replaced by 1 when d_j is set to zero. Preliminary tests indicate that if the diagnostic quantity is above 0.999 then the truncation has negligible effect on V.

Another important method of accelerating the GCV calculations by avoiding the final reduction to diagonal form in the SVD was given by Elden (1984). This involves stopping the evaluation of the singular value decomposition at the intermediate step of the reduction of J_2 to a bidiagonal form, then forming an expression for $V(\lambda)$.

Description

The package has three main subroutine drivers. The first driver, dtpss for thin plate smoothing splines, is the most efficient and the most restrictive, allowing covariates only in the case where the replication pattern is the same as that found in the design. The second driver, dptpss for partial thin plate smoothing splines, handles general covariates and in turn calls the third driver, dsnsm which handles penalized least squares problems with a semi-norm penalty. After a call to dtpss or dptpss the subroutine dpred can be called to evaluate predicted values for additional points not in the design.

Replicates are handled in *dtpss* and *dptpss* using the following routines. The subroutine *dreps* sorts the \mathbf{x} vectors and returns \mathbf{C}_1 and the information necessary for the routines *duni* and *dsuy* (used only in *dtpss*). Subroutine *duni* reduces a matrix (\mathbf{T} or \mathbf{K}) to the corresponding matrix with unique entries (\mathbf{T}_U or \mathbf{K}_U). The routine *dsuy* sorts \mathbf{y} and computes $\mathbf{B}_1^T\mathbf{y}$ and the sum of squares due to replication.

The subroutine dtpss, the thin plate spline driver, calls the routine dsetup to create the matrices $\mathbf{C}_1\mathbf{K}_U\mathbf{C}_1^T$ and $\mathbf{C}_1[\mathbf{T}_U:\mathbf{S}_{1U}]$ from the design points x_i , i = 1, 2, ..., n using the routines dmakek and dmaket. The LINPACK routine dgrdc is called to decompose $C_1[T_U:S_{1U}]$ into its QR decomposition FG, followed by the routine dftkf to calculate $\mathbf{F}^{\mathrm{T}}\mathbf{C}_{1}\mathbf{K}_{U}\mathbf{C}_{1}^{\mathrm{T}}\mathbf{F}$. Dsgdc1 does the Cholesky decomposition of $\mathbf{F}_2^T \mathbf{C}_1 \mathbf{K}_U \mathbf{C}_1^T \mathbf{F}_2$ and the singular value decomposition of the Cholesky factor. Dgcv1 uses these results to compute the generalized cross validation estimate of λ and the corresponding estimates of the other parameters. The work in dgcvl is divided into application of the rotations by \mathbf{F}^{T} in drsap, optimization of the $V(\lambda)$ function in dvlop, computation of predictive mean square error (if requested) in dpmse, creation of the coefficient vector in dcfcr1, creation of the predicted values in dpdcr, and creation of the diagonal of $A(\hat{\lambda})$ in ddiag. Subroutine dvlop calls dvmin to minimize $V(\lambda)$ by repeated calls to dvl. The minimization is done by an initial grid search in the $ln(n\lambda)$ scale followed by a golden ratio search in the neighborhood of the minimizing grid point. The input variable ntbl controls the resolution of the initial grid search. A value for ntbl of 100 or greater is recommended to ensure that the global optimum is located. If a plot of $V(\lambda)$ versus $\ln(n\lambda)$ indicates that a local optimum has been obtained the user may either increase the value of ntbl or use the option to specify a reduced range for the search. The grid of $ln(n\lambda)$ values is returned along with the corresponding $V(\lambda)$ values in the variable tbl. The variable auxtbl is returned containing $\hat{\lambda}$, $V(\hat{\lambda})$, V(0) and $V(\infty)$.

The driver *dptpss* for partial thin plate splines calls routines *dreps*, *dmaket*, *duni*, and *dmakek* to set up [T:S], $[T_U:S_{1U}]$ and K_U . These are fed to *dctsx* to create the matrices Σ and X which are used by the driver *dsnsm*.

The subroutine dsnsm is a general driver for penalized least squares problems with a semi-norm penalty. It calls ddcom which decomposes Σ and \mathbf{X} and returns information used by dgcv to find $\hat{\lambda}$, θ_{λ} , and other results. The work in ddcom is split into the decomposition of Σ in a call to dsgdc and the transformation and decomposition of the design in dcrtz and dzdc which in turn calls dtsvdc or dsvdc to perform the singular value decomposition. The work in dgcv is divided into the same subroutines as dgcvl with the exception that dcfcrl is replaced by dcfcr.

In the general case, the driver dsnsm allows an option to use a truncation singular value decomposition through the routine dtsvdc which preprocesses the design matrix \mathbf{J}_2 to reduce the dimensionality before invoking dsvdc (see Appendix 3). The truncation tolerance, $\tau \times \rho$ is passed to dtsvdc as the parameter minrat. The drivers dtpss and dptpss would not benefit from truncation in the SVD calculation so they use the LINPACK routine dsvdc.

Simulation Applications: When GCVPACK is used for simulation studies the option to compute the predictive mean square error should be used. The known "true" response is input in the variable *adiag* and the predictive mean square error, $R(\lambda)$, is returned, along with $V(\lambda)$, in the variable *tbl*. It is recommended that plots of $V(\lambda)$ and $R(\lambda)$ versus $\ln(n\lambda)$ be used to evaluate the success of the GCV function in finding the optimal λ (the λ which minimizes predictive mean square error). The variable *auxtbl* contains $R(\lambda)$, R(0) and $R(\infty)$.

The decomposition of the **X** matrix requires the most intensive computation. The subroutines *dtpss* and *dptpss* are both set up to take advantage of the savings in computation that exist for multiple response vectors with the same design. To modify *dtpss* to handle a problem with more than one response vector all code up to and including the call to *dsgdc1* is executed once. A loop can be added to execute the remaining code for each **y** vector. In practice this modification would involve adding only a few lines of code.

To modify dptpss, or any other driver which calls dsnsm, a loop must be added in dsnsm. In dsnsm there are two subroutines, ddcom which needs to be executed once, and dgcv which must be executed once for each response vector. In dptpss, after the call to dsnsm, a transformation is applied to the coefficient vector. This must be done to the coefficient vector corresponding to each y vector.

Related Algorithms

The numerical linear algebra in our routines is performed using the LINPACK (Dongarra et al., 1979) routines. The introductory comments of each GCVPACK routine list which LINPACK and BLAS (Basic Linear Algebra Subroutines) routines are called directly or indirectly. There is one machine—dependent constant, the relative machine precision, which is used in these routines to determine error conditions caused by ill-conditioning, but that constant is computed each time it is needed.

The present work generalizes algorithms for ridge regression of Golub, Heath, and Wahba (1979) and Bates and Wahba

(1982) which use the singular value decomposition. Elden (1977) gives an algorithm which terminates the singular value decomposition at an intermediate step, reducing **X** to a bidiagonal form, thereby saving time (see the **Test Results** section). This could be incorporated into GCVPACK but we have not done so yet.

Wendelberger (1981) implemented an algorithm for thin plate splines based on eigenvalue-eigenvector decompositions for one-dimensional and multi-dimensional thin plate smoothing splines. Hutchinson (1984) developed an algorithm for thin plate splines with large data sets using the thin plate basis functions of Wahba (1980b); see Appendix 2.

Reinsch (1967) initially proposed a fast algorithm for fixed λ using a Cholesky decomposition (see De Boor (1978)). In the one-dimensional case, the penalty can be written as a product of matrices with only 2m-1 non-zero diagonals. Hutchinson and de Hoog (1985) give an O(n) algorithm for computing $V(\lambda)$ using a Cholesky decomposition of these matrices. See also O'Sullivan (1985). GCVPACK is not designed to take advantage of the unique structure of one dimensional polynomial smoothing splines, and runs much slower than the code of Hutchinson and de Hoog (1985) in this case.

O'Sullivan, Yandell and Raynor (1986) developed algorithms for smooth generalized linear models based on a Cholesky decomposition of $\mathbf{X}^{T}\mathbf{X} + n\lambda\mathbf{I}$. Green (1985) and Green and Yandell (1985) presented algorithms for penalized likelihood schemes which include generalized linear models and other iteratively reweighted least squares methods. They present a one-dimensional algorithm based on Reinsch (1967) and a general algorithm based on the Cholesky decomposition. They have also incorporated an iterative algorithm using the SVD to automate the choice of $\hat{\lambda}$, but it needs extensive testing to determine if it is stable. Shiau (1985) developed algorithms for a particular class of partial splines consisting of discontinuities of f or higher order derivatives at known or unknown points. This includes a one-dimensional algorithm based on Hutchinson and de Hoog (1985) and a multidimensional algorithm based on the Cholesky decomposition.

Test Results

The package and drivers have been tested for internal consistency and for accuracy against other known algorithms. Here we present some timing results to show that the methods are feasible for relatively large data sets and to offer insight into which portions of the code should be avoided, if possible. For example, the code allows the computation of the diagonal of $\mathbf{A}(\hat{\lambda})$ for forming diagnostics (Eubank, 1984) but this calculation

alone can take 15% or more of the total execution time.

All timing runs were performed on a Vax-11/750 computer with a floating point accelerator and running the 4.2 BSD *UNIX*TM operating system. We quote two sets of times for the example: one using the driver *dtpss* and the other using *dptpss*. Each of the drivers was timed twice: first using the Fortran version of the Basic Linear Algebra Routines (BLAS) then using Assembler Language BLAS. As explained in Dongarra et al. (1979), the BLAS are a set of low-level routines that perform such elementary tasks as accumulation of dot products and, by replacing them with Assembler language versions, the Linpack routines can be made to run faster.

The design for the example is a 9 by 9 factorial in \mathbf{x}_1 and \mathbf{x}_2 with one covariate, \mathbf{x}_2^2 . Two replicate observations were simulated at each of the 81 design points. Thus n = 162, k = 81, m = 2, d = 2 and c = 1. Our timing results are shown in Tables 1 and 2. The total times are slightly greater than the sum of the times spent in the lower level subroutines since the driver routines have to do some definition of pointers, etc.

The first thing to notice from these tables is that *dtpss* is strongly preferred over *dptpss* for this example since it executes approximately 3 times faster. In general, if *dtpss* can solve the problem, it will do so more quickly. Also, the Assembler BLAS speed things up considerably with most of the gain being in the call to the Linpack SVD routine *dsvdc*.

Table 2: Example 1 using *dptpss*

We have divided the time for dsvdc into two subsections, bidiag and diag. Elden (1984) gave a method of expressing the GCV function $V(\lambda)$ avoiding the diag step. This would result in considerable savings in the dsgdcl or ddcom routines. This savings is offset by the calculations in dgcvl or dgcv becoming more complicated and, possibly, taking longer. However, since those routines take up much less time than diag, we would expect that the overall savings would be worthwhile.

Notice that the calculation of the diagonal of $\mathbf{A}(\hat{\lambda})$ in *ddiag* is comparatively expensive – usually around 15% of the total execution time. If this optional information is not going to be used, it should not be calculated.

In circumstances where there are multiple \mathbf{y} vectors being analysed for the same design and penalty matrices, such as in Monte-Carlo runs, the decomposition portion, dsgdcl or ddcom, should be called only once while the analysis portion, dgcvl or dgcv, called for each \mathbf{y} . The analysis portion represents less than 5% of the total time if the calculation of the diagonal of $\mathbf{A}(\hat{\lambda})$ is not undertaken.

The sorting method used in *dreps* is a comparatively primitive sort (a modification of the bubble sort) but, even so, the time taken by *dreps* is a small percentage of the total time. It would be possible to speed up this step by using a more sophisticated sort, but it doesn't appear worthwhile. Also, the evaluation of $V(\lambda)$ after the matrices are decomposed is very quick. In these runs the variable *ntbl* was set to 200 so both $V(\lambda)$ and the

mean squared error of prediction (since the data were simulated) were evaluated at 200 different values of λ . Even with 200 evaluations *dvlop* and *dpmse* each represented, at most, 2% of the execution time.

Appendix 1. – replicates and rank-deficient penalty matrices

Because the functions E_m defined in (2.3) are increasing functions of the length of their argument, the matrix \mathbf{K} defined in (2.4) will be close to singular if $\|\mathbf{x}_i - \mathbf{x}_j\|$ is very small for some $i \neq j$. To avoid an indeterminacy in the parameters of the thin-plate spline, we determine replicates by comparing $\|\mathbf{x}_i - \mathbf{x}_j\|$ to a tolerance level rather than checking for $\mathbf{x}_i = \mathbf{x}_j$. The tolerance level is calculated as 100 times the relative machine precision times the length of the diagonal of the smallest rectangle which encloses the $\mathbf{x}_i, i = 1, \ldots, n$. In all our test cases, this check has been adequate to ensure that the matrix $\mathbf{F}_2^T \mathbf{K} \mathbf{F}_2$ is computationally positive definite.

It is important to note that the determination of replicates involves sorting the \mathbf{x}_i , $i = 1, \ldots, n$, in increasing lexicographic order. That is,

the rows of
$$\begin{bmatrix} 1 & 1 \\ 2 & 1 \\ 3 & 1 \\ 4 & 1 \\ 1 & 2 \\ 2 & 2 \\ 3 & 2 \\ 4 & 2 \end{bmatrix}$$
 would be re-ordered as
$$\begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 2 & 1 \\ 2 & 2 \\ 3 & 1 \\ 3 & 2 \\ 4 & 1 \\ 4 & 2 \end{bmatrix}$$

As mentioned in the **Test Results** section, the sorting algorithm is comparatively primitive (a modification of a bubble sort) and, even though it does not take a substantial percentage of the total execution time, it is to the user's advantage to pass the argument *des* to *dtpss* or *dptpss* with the rows in increasing lexicographic order, if possible, as the sorting time will be minimized.

Replicates are determined in such a way as to avoid a singular penalty matrix because a singular penalty matrix has a different effect for the thin-plate smoothing spline (or partial spline) than it does for the case of a general design matrix with a semi-norm penalty. In the general case, we determine the null space of the penalty so unexpected singularities simply increase the dimension of the null space and that part of the parameter vector is incorporated into the β . Ordinary regression is used to determine β and we assume (and check) that the part of the design matrix corresponding to β is non-singular. Unless the singularity in the penalty corresponds to a singularity in the

design, everything works well.

In the case of a thin-plate smoothing spline the least squares part of the objective function (2.6) uses the same matrix ($\mathbf{F}_2^T\mathbf{K}\mathbf{F}_2$) as the penalty part. Thus, when the penalty is rank-deficient, the "design" matrix (in the regression sense) is also rank deficient and the parameters which lie in the extended null space of the penalty are indeterminant. This can be seen from the form of (2.6). If there are singular values of zero, the corresponding parameters have no effect on the predictions and thus do not enter into the objective function $S_{\lambda}(\beta,\delta)$. There is a parameter vector which can be calculated using (2.9) even with some zero singular values but the part corresponding to the zero singular values can be changed to an arbitrary value without affecting the predictions so, in particular, it could be set to zero. More specifically, consider the last two terms in the last line of (2.6), after the Cholesky decomposition:

$$\frac{1}{n} \| \mathbf{w}_2 - \mathbf{L}^T \mathbf{L} \boldsymbol{\delta} \| + \lambda \boldsymbol{\delta}^T \mathbf{L}^T \mathbf{L} \boldsymbol{\delta} . \tag{A1.1}$$

If L is not of full row rank, any δ satisfying

$$\mathbf{L}^{\mathrm{T}}\mathbf{L}\mathbf{w}_{2} = [(\mathbf{L}^{\mathrm{T}}\mathbf{L})^{2} + n\lambda \mathbf{L}^{\mathrm{T}}\mathbf{L}]\delta$$

minimizes (A1.1), and in particular we could take

$$\delta = (\mathbf{L}^{\mathrm{T}}\mathbf{L} + n\,\lambda\,\mathbf{I})^{-1}\,\mathbf{w}_{2}.$$

However, we have chosen not to write the special code that would be required to handle this case. We have eliminated one source of a computationally singular penalty matrix for the thin plate spline by merging nearly replicated data points. If the computational singularity of $\mathbf{F}_2^T\mathbf{K}\mathbf{F}_2$ is due to other than nearly replicated data points, i.e., due to very large sets of highly irregularly spaced data, the user should consider using thin plate basis functions as described in Appendix 2.

Appendix 2. – partial splines with basis functions

One can use the algorithm for a general design matrix with semi-norm penalty to find partial thin-plate smoothing splines determined by basis functions centered at specified nodes. See Shiau, Wahba, and Johnson (1985). For example, consider the model

$$y_i = \int \cdots \int K(\mathbf{x}_i, \mathbf{x}) f(\mathbf{x}) d\mathbf{x} + \varepsilon_i$$
$$= L_i f + \varepsilon_i .$$

The estimate f_{λ} of f is the minimizer, in an appropriate space, of

$$\frac{1}{n} \sum_{i=1}^{n} (y_i - L_i f)^2 + \lambda J(f)$$
 (A2.1)

where J(f) is an appropriate (quadratic) roughness penalty. If we can approximate f_{λ} by

$$f_{\lambda} = \sum_{i=1}^{b} \theta_i B_i$$

where $\{B_i\}$ are suitably chosen basis functions, then we can define the ij'th entry of \mathbf{X} as L_iB_j and the matrix Σ by $J(\Sigma \theta_j B_j) = \mathbf{\theta}^T \Sigma \mathbf{\theta}$.

The thin plate basis functions were proposed for this purpose by Wahba (1980a). Starting with a set of suitably distributed distinct nodes $\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_b$, the approximation is

$$f_{\lambda}(\mathbf{x}) = \sum_{i=1}^{t} \beta_{i} \, \phi_{i} \, (\mathbf{x}) + \sum_{i=1}^{b} \delta_{i} E_{m} \, (\mathbf{x} - \mathbf{t}_{i})$$
 (A2.2)

where $\delta = (\delta_1, \dots, \delta_b)^T$ must satisfy

$$\sum_{i=1}^{b} \delta_i \phi_j(\mathbf{t}_i) = 0 , j=1, \dots t .$$

If f_{λ} is required to be of the form (A2.2), then (A2.1) becomes

$$S_{\lambda}(\beta, \delta) = \frac{1}{n} \| \mathbf{y} - \mathbf{T}\beta - \mathbf{K}\delta \|^{2} + \lambda \delta^{T} \mathbf{K}_{B} \delta$$

subject to $\mathbf{T}_{R}^{\mathrm{T}} \mathbf{\delta} = \mathbf{0}$, with

$$\{\mathbf{T}_B\}_{ij} = \phi_j(\mathbf{t}_i) \ .$$

Here, **T** is $n \times t$ and **K** is $n \times b$, with entries

$$\begin{split} \{\mathbf{T}\}_{ij} &= L_i \phi_j \ , \\ \{\mathbf{K}\}_{ij} &= L_i E_m (\bullet - \mathbf{t}_j) \ , \end{split}$$

and \mathbf{K}_B is $b \times b$ with entries

$$\{\mathbf{K}_B\}_{ij} = E_m(\mathbf{t}_i - \mathbf{t}_j) .$$

If we are interested simply in evaluation functionals, then $L_i f = f(\mathbf{x}_i)$. The matrices \mathbf{T}_B and \mathbf{K}_B remain the same, but the matrices \mathbf{T} and \mathbf{K} have entries

$$\{\mathbf{T}\}_{ij} = \phi_j(\mathbf{x}_i) ,$$

$$\{\mathbf{K}\}_{ij} = E_m(\mathbf{x}_i - \mathbf{t}_j) .$$

We take a QR decomposition

$$\mathbf{T}_B = \mathbf{FG} = [\mathbf{F}_1 : \mathbf{F}_2] \begin{bmatrix} \mathbf{G}_1 \\ \mathbf{0} \end{bmatrix} = \mathbf{F}_1 \mathbf{G}_1$$

and use this to construct the parameter vector

$$\theta = \begin{bmatrix} \beta \\ \zeta \end{bmatrix}$$
 , with $\delta = F_2 \zeta$,

and to create the design matrix

$$\mathbf{X} = [\mathbf{T} : \mathbf{KF}_2]$$

and penalty matrix

$$\Sigma = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{F}_2^{\mathrm{T}} \mathbf{K}_B \, \mathbf{F}_2 \end{bmatrix} .$$

We then proceed as in the case of a general design matrix with a semi-norm penalty as described earlier.

Hutchinson's (1984) code implements thin plate basis functions for the case $L_i f = f(\mathbf{x}_i)$, where b is chosen to be much less than n when n is large. Hutchinson's code, or the partial thin plate smoothing spline code described here, should be considered in the case that n is very large or $\mathbf{F}_2^T \mathbf{K} \mathbf{F}_2$ of (2.6) is computationally singular.

Covariates and replicates are handled as before and enter in the same way as for partial spline models. Considering here only the case of no replicates, the model with covariates is

$$f_{\lambda}(\mathbf{x},\mathbf{s}) = \sum_{i=1}^{t} \beta_{i} \phi_{i}(\mathbf{x}) + \sum_{i=1}^{b} \delta_{i} E_{m}(\mathbf{x} - \mathbf{t}_{i}) + \sum_{j=1}^{c} \alpha_{j} \psi_{j}(\mathbf{x},\mathbf{s}) .$$

The objective function for a fixed λ becomes

$$S_{\lambda}(\alpha,\beta,\delta) = \frac{1}{n} \| \mathbf{y} - \mathbf{S}\alpha - \mathbf{T}\beta - \mathbf{K}\delta \|^{2} + \lambda \delta^{T}\mathbf{K}_{B}\delta$$

subject to $\mathbf{T}_{B}^{\mathrm{T}} \mathbf{\delta} = \mathbf{0}$, in which **S** is $n \times c$ with entries

$$\{\mathbf{S}\}_{ij} = L_i \psi_j(\bullet, \mathbf{s}_i)$$
,

or, for evaluation functionals,

$$\{\mathbf{S}\}_{ij} = \psi_j(\mathbf{x}_i, \mathbf{s}_i) .$$

The design matrix becomes

$$\mathbf{X} = [\mathbf{T} : \mathbf{S} : \mathbf{KF}_2]$$

with parameter vector

$$\theta = \begin{bmatrix} \beta \\ \alpha \\ \zeta \end{bmatrix} .$$

The penalty Σ has the same form, with the addition of rows and columns of zeroes corresponding to α . One would then proceed with the general design matrix with semi-norm penalty.

Appendix 3. – the truncated singular value decomposition

The following theorem of Mirsky (1960) provides a bound for the error in the singular values when using an approximation to a matrix.

Theorem 1: Let **X** and **Y** be $n \times p$ $(n \ge p)$ matrices with singular value decompositions **UDV**^T and **RSW**^T respectively.

Denote the ordered singular values of **X** as $\{d_i\}, i=1, \dots, p$ with $d_1 \ge d_2 \ge \dots \ge d_p$ and the ordered singular values of **Y** as $\{s_i\}, i=1, \dots, p$. Then

$$\sum_{i=1}^{p} (d_i - s_i)^2 \le \| \mathbf{X} - \mathbf{Y} \|_F^2 = tr \left[(\mathbf{X} - \mathbf{Y})^{\mathrm{T}} (\mathbf{X} - \mathbf{Y}) \right]$$

We will take advantage of this theorem to calculate the SVD of a matrix \mathbf{X}_{a^*} which is close to \mathbf{X} in the sense that $\|\mathbf{X} - \mathbf{X}_{a^*}\|$ is small but is better conditioned than is \mathbf{X} so the iterative portion of the SVD tends to converge faster and the computational burden is reduced. First, we take a pivoted QR decomposition of \mathbf{X} using the pivoting scheme from LINPACK (Dongarra et al., 1979). That is, we determine \mathbf{Q} , $n \times n$ orthogonal, \mathbf{R} , $n \times p$ and zero below the main diagonal, and \mathbf{E} , a $p \times p$ permutation matrix, such that

$$XE = QR \tag{A3.1}$$

and **R** has the property that

$$r_{a^*,a^*}^2 \ge \sum_{i=a^*}^{j} r_{i,j}^2 \quad (j=a^*,a^*+1,\cdots,p).$$
 (A3.2)

If we take the SVD of \mathbf{R}_p , the triangular matrix composed of the first p rows of \mathbf{R} , as

$$\mathbf{R}_{p} = \mathbf{K}\mathbf{D}\mathbf{L}^{\mathrm{T}} \tag{A3.3}$$

we can produce the SVD of X as

$$\mathbf{X} = \mathbf{Q}_p \mathbf{K} \mathbf{D} \mathbf{L}^{\mathrm{T}} \mathbf{E}^{\mathrm{T}} = \mathbf{U} \mathbf{D} \mathbf{V}^{\mathrm{T}}$$
 (A3.4)

where \mathbf{Q}_p is the $n \times p$ matrix composed of the first p columns of \mathbf{Q} and $\mathbf{U} = \mathbf{Q}_p \mathbf{K}$ is $n \times p$ while $\mathbf{V} = \mathbf{E} \mathbf{L}$ is $p \times p$ and orthogonal. This method would not, however, produce better conditioning for the SVD algorithm since the singular values of \mathbf{R}_p are the same as the singular values of \mathbf{X} .

To provide better conditioning, we truncate the matrix \mathbf{R}_p after the a^* 'th row and take the SVD of the resulting $n \times a^*$ matrix \mathbf{R}_{a^*} ($a^* \le p$) as

$$\mathbf{R}_{a^*} = \mathbf{K}_{a^*} \mathbf{D}_{a^*} \mathbf{L}_{a^*} \tag{A3.5}$$

where \mathbf{K}_{a^*} is $a^* \times a^*$ and \mathbf{L}_{a^*} is $a^* \times p$. The diagonal elements of \mathbf{D}_{a^*} are no longer the singular values of \mathbf{X} but now represent the singular values of a matrix

$$\mathbf{X}_{a^*} = \mathbf{Q}_p \begin{bmatrix} \mathbf{R}_{a^*} \\ 0 \end{bmatrix} \mathbf{E}^{\mathrm{T}} \tag{A3.6}$$

which is different from X. However,

$$\|\mathbf{X} - \mathbf{X}_{a^*}\|_F = \left[\sum_{i=a^*+1}^p \sum_{j=i}^p r_{i,j}^2\right]^{1/2}$$
 (A3.7)

so we can choose a^* to be as small as possible subject to the

constraint that

$$\frac{\parallel \mathbf{X} - \mathbf{X}_{a^*} \parallel_F}{\parallel \mathbf{X} \parallel_F} \le \tau \rho \tag{A3.8}$$

where ρ is the relative machine precision (the smallest number such that $1+\rho>1$ in floating point arithmetic) and τ is a small multiplier.

We initially choose τ as unity but increase it if the LIN-PACK singular value decomposition routine (dsvdc) fails to converge. When such a convergence failure occurs, the user can either increase the number of iterations per singular value allowed in dsvdc (we increase this from 30 to 90) or increase τ or both. To increase the maximum allowable number of iterations, change the value of MAXIT in dsvdc.

Allowing τ to get too large can result in inaccuracies in the calculation of V. The effect of the truncation is measured by the diagnostic ratio defined in (5.7). In general, values of τ above 100 are not recommended.

The double sum on the right of (A3.7) is easily evaluated a row at a time starting at the p'th row until the constraint (A3.8) is violated and the smallest a^* is determined.

By theorem 1, if $\{d_i\}$, i=1,...,p are the ordered singular values of \mathbf{X} and $\{d_{i,a^*}\}$, i=1,...,p are the ordered singular values of \mathbf{X}_{a^*} , then

$$\left(\sum_{i=1}^{p} (d_i - d_{i,a^*})^2\right)^{1/2} \le \tau \rho \| \mathbf{X} \| = \tau \rho \left(\sum_{i=1}^{p} d_i^2\right)^{1/2} \tag{A3.9}$$

If $n \le p$, the same procedure is applied to \mathbf{X}^T .

Major Changes in Second Release

This is a listing of the major changes to Gcvpack for the second release. Users who call only the drivers dptpss.f and dtpss.f will not have to make any modifications to their calling routines. Users who call the driver dsnsm.f must add the argument factor to the calling sequence (start with a value of 1.0) and must declare dout to be of length 5 rather than 4. All users must note that the search for lambda hat is now done in the log base 10 scale rather than the natural log scale. This will change the output from all drivers. Users who call any other routines must be very careful to note the changes in calling sequences listed below. We do not expect to release another version of Gcvpack after this one. You must replace all of the release 1 routines with release 2 routines to insure correct computation. The set of necessary linpack routines has not changed.

affected routines $ddsdc.f \dagger, ddcom.f, dcrtz.f **, ddsa$

description

ddsdc.f †, ddcom.f , dcrtz.f **, dzdc.f **	ddsdc.f is replaced with $dcrtz.f$, $dzdc.f$.
ddcom.f, $dzdc.f$	Nonzero info and svals from dsvdc are now returned in npsing and svals.
dsgdc1.f	Nonzero $info$ and $svals$ from $dsvdc$ are now returned in p and $svals$.
dptpss.f, dsnsm.f, dtpss.f	Nonzero info and svals from dsvdc are now returned in iout (1) and svals.
<pre>dpdcr.f *, ddiag.f **, dgcv.f , dgcv1.f</pre>	Calculation of the diagonal of the hat matrix has been removed from $dpdcr.f$ and is now done in the new routine $ddiag.f$.
<pre>dtpss.f , dsnsm.f , dptpss.f , dgcv1.f, dgcv.f</pre>	<i>Iout</i> and <i>dout</i> are now assigned as early as possible to return more information when <i>info</i> is positive.
dgcv.f, dgcvl.f, dpmse.f, dptpss.f, dsnsm.f, dtpss.f, dvl.f, dvlop.f	Lambda values are expressed as log base 10 rather than natural log.
dsuy.f *, dreps.f *, dtpss.f , dptpss.f	The argument dfrep is removed from the calling sequences of $\mathit{dsuy}.f$ and $\mathit{dreps}.f$.
dvlop.f*, dgcvl.f, dgcv.f	The argument $npar$ is removed from the calling sequence of $dvlop.f$.
dcfcr.f *, dgcv.f	The argument $fgaux$ is removed from the calling sequence of $dcfcr.f$.
ddcom.f, dcrtz.f*	The argument lwa is removed from the calling sequence of $dcrtz.f$.
ddcom.f *, dsnsm.f *, dzdc.f *	The argument <i>factor</i> is added to allow control over the amount of truncation.
dsnsm.f	The argument <i>dout</i> must be declared with length 5 rather than length 4. The truncation ratio is now returned in $dout(5)$.
ddcom.f*, dzdc.f*, dtsvdc.f*	The Frobenius norm of $R - R_k$ is now returned as an argument.
<pre>dcfcr.f , dcfcr1.f, dgemv.f **, ddiag.f , dpdcr.f , dpmse.f , dpred.f , drsap.f</pre>	The routine <i>dgemv.f</i> is called to perform matrix multiplication. (<i>Dgemv.f</i> is from the extended BLAS)
testtpss.out, testptpss.out	Changes due to the switch from natural log to log base 10 and reformatting of output.

fort. 8†, testtpss.in**, testptpss.in**, testtpss.f, testptpss.f	The input files testtpss.in and testptpss.in replace fort. 8 and are now read as standard input.
inteqn.f **, inteqn.in **, inteqn.out **, mktpar.f **,	Routines and files used for new integral equation test driver $inteqn.f$.

mkxys.f **

Non-zero Error Codes from Driver Routines

Below are all the error codes which may arise during use of the drivers dptpss, dsnsm and dtpss. Refer to Description section and code for further details.

Non-zero Error Codes from dptpss

Code	Occured In	Meaning
-2	dvmin	$log(nobs*lamhat) \ge lamlim(2) $ (not fatal)
-1	dvmin	$\log(nobs*lamhat) \leq lamlim(1)$ (not fatal), will occur if limits on lambda hat are input by user and are equal.
1	dptpss	dimension error (nobs ≤ 0 or $m \leq 0$ or $dim \leq 0$ or $ntbl < 0$ or $ntbl > ldtbl$ or $2*m - dim \leq 0$)
2	dptpss	error in $dreps$, the first $ncov 1$ columns of s do not duplicate the replication structure of des
3	dptpss	$lwa \ (length \ of \ work) < ncts \ 1*(nobs + nuobs + 1) + npar*(nobs + npar + 1) + (npar - nnull)*(npar - 2*nnull + 2+nobs)+npar+nobs$
4	dptpss	liwa (length of $iwork$) < $3*nobs - ncts 1$
5	dptpss	error in dmaket (error in creation of T)
6	dptpss	sigma is rank deficient
1001*	dsnsm	dimension error $(nobs \le 0 \text{ or } npar \le 0 \text{ or } nnull \le 0 \text{ or } (npar - nnull) \le 0)$
1002*	dsnsm	lwa (length of work) $<$ (npar - nnull)*(npar - 2*nnull + 2 + nobs) + npar + nobs
1003*	dsnsm	liwa (length of $iwork$) < $2*npar - nnull$
1004*	dsnsm	error in $ntbl$ ($ntbl < 0$ or $ntbl > ldtbl$)
1101*	ddcom	dimension error (nobs ≤ 0 or npar ≤ 0 or nnull ≤ 0 or (npar - nnull) ≤ 0 or $ldx < nobs$ or $ldx < npar$)
1102*	ddcom	$ldcaux$ (length of $dcaux$) < $(npar - nnull)^2 + 2*npar - nnull$
1103*	ddcom	lwa (length of work) < (npar - nnull)* (nobs - nnull + 1) + nobs
1104*	ddcom	liwa (length of iwork) < npar - nnull
1111*	dsgdc	calculated nnull is smaller than input nnull
1121	dcrtz	error in dtrsl, R is singular
1131*	dzdc	$lwa \ (length \ of \ work) < (npar - nnull)* (nobs - nnull) + npar - nnull + nobs$
1132	dzdc	transpose of J_2 is necessary (npar > nobs) but npar > ldx
1133*	dzdc	failure to converge in dsvdc called from dtsvdc (using $\mathbf{J}_2^{\mathrm{T}}$)
1134	dzdc	failure to converge in $dsvdc$ (using \mathbf{J}_{2}^{T}), this error can usually be cured by increasing the parameter MAXIT in the LINPACK routine $dsvdc$
1135*	dzdc	failure to converge in dsvdc called from dtsvdc

for new integral equation test driver integn.f.

^{*} Calling sequence changed, ** New routine or file, † Deleted routine or file

1136	dzdc	failure to converge in <i>dsvdc</i> , this error can usually be cured by increasing the parameter MAXIT in the LINPACK routine <i>dsvdc</i>
1201*	dgcv	dimension error ($nobs \le 0$ or $npar \le 0$ or $nnull \le 0$ or $(npar - nnull) \le 0$)
1202*	dgcv	error in <i>ntbl</i> ($ntbl < 0$ or $ntbl > ldtbl$)
1203*	dgcv	$ldcaux$ (length of $dcaux$) < $(npar - nnull)^2 + 2*npar - nnull$
1204*	dgcv	lwa (length of work) < (npar - nnull) + nobs
1205	dgcv	lamlim(1) > lamlim(2)
1211	dvlop	svals(1) = 0.0d0
1212*	dvlop	npsing is incorrect
1213*	dvlop	lamlim(1) > lamlim(2)
1221	dcfcr	error in <i>dtrco</i> , G is singular
1222	dcfcr	error in dtrsl, R is singular

^{*}Should not occur in normal circumstances

Non-zero Error Codes from dsnsm

Code	Occured In	Meaning
-3	dsgdc	calculated nnull is larger than input nnull (not fatal)
-2	dvmin	$log(nobs*lamhat) \ge lamlim(2) $ (not fatal)
-1	dvmin	$\log(nobs*lamhat) \le lamlim(1)$ (not fatal), will occur if limits on lambda hat are input by user and are equal.
1	dsnsm	dimension error $(nobs \le 0 \text{ or } npar \le 0 \text{ or } nnull \le 0 \text{ or } (npar - nnull) \le 0)$
2	dsnsm	lwa (length of work) < (npar - nnull)* (npar - 2*nnull + 2+nobs) + npar + nobs
3	dsnsm	liwa (length of $iwork$) < $2*npar - nnull$
4	dsnsm	error in <i>ntbl</i> ($ntbl < 0$ or $ntbl > ldtbl$) or $\tau < 0$
101	ddcom	$\tau < 0$ or dimension error (nobs ≤ 0 or npar ≤ 0 or nnull ≤ 0 or (npar - nnull) ≤ 0 or $ldx < nobs$ or $ldx < npar$)
102*	ddcom	$ldcaux$ (length of $dcaux$) < $(npar - nnull)^2 + 2*npar - nnull$
103*	ddcom	lwa (length of work) < (npar - nnull)* (nobs - nnull + 1) + nobs
104*	ddcom	liwa (length of iwork) < npar - nnull
111	dsgdc	calculated nnull is smaller than input nnull
121	dcrtz	error in dtrsl, R is singular
131*	dzdc	lwa (length of work) < (npar - nnull)* (nobs - nnull) + npar - nnull + nobs
132	dzdc	τ<0
133	dzdc	transpose of J_2 is necessary (npar > nobs) but npar > ldx
134	dzdc	failure to converge in $dsvdc$ called from $dtsvdc$ (using \mathbb{J}_2^T), this error can usually be cured by increasing the parameter MAXIT in the LINPACK routine $dsvdc$ or by increasing the value of the argument τ to $dsnsm$ (see discussion in TR775 (rev.))
135	dzdc	failure to converge in $dsvdc$ (using $\mathbf{J}_2^{\mathrm{T}}$), this error can usually be cured by using the truncation option or by increasing the parameter MAXIT in the LINPACK routine $dsvdc$
136	dzdc	failure to converge in $dsvdc$ called from $dtsvdc$, this error can usually be cured by increasing the parameter MAXIT in the LINPACK routine $dsvdc$ or by increasing the value of the argument τ to $dsnsm$ (see discussion in TR775 (rev.))
137	dzdc	failure to converge in $dsvdc$ (using $\mathbf{J}_{2}^{\mathrm{T}}$), this error can usually be cured by using the truncation option or by increasing the parameter MAXIT in the LINPACK routine $dsvdc$
201*	dgcv	dimension error (nobs ≤ 0 or npar ≤ 0 or nnull ≤ 0 or (npar - nnull) ≤ 0)
202*	dgcv	error in <i>ntbl</i> ($ntbl < 0$ or $ntbl > ldtbl$)
203*	dgcv	$ldcaux$ (length of $dcaux$) < $(npar - nnull)^2 + 2*npar - nnull$

204*	dgcv	lwa (length of work) < (npar - nnull) + nobs
205	dgcv	lamlim(1) > lamlim(2)
211	dvlop	svals(1) = 0.0d0
212	dvlop	npsing is incorrect
213*	dvlop	lamlim(1) > lamlim(2)
221	dcfcr	error in dtrco, G is singular
222	dcfcr	error in dtrsl, R is singular

^{*}Should not occur in normal circumstances

Non-zero Error Codes from dtpss

Code	Occured In	Meaning
-2	dvmin	$log(nobs*lamhat) \ge lamlim(2) $ (not fatal)
-1	dvmin	$\log(nobs*lamhat) \leq lamlim(1)$ (not fatal), will occur if limits on lambda hat are input by user and are equal.
1	dtpss	dimension error (nobs ≤ 0 or $m \leq 0$ or $dim \leq 0$ or $ntbl < 0$ or $ntbl > ldtbl$ or $2*m - dim \leq 0$)
2	dtpss	error in dreps, covariates do not duplicate the replication structure of des
3	dtpss	lwa (length of work) < nuobs*(2 + ncts + nuobs) + nobs
4	dtpss	liwa (length of $iwork$) < $2*nobs + nuobs - ncts$
11	dsetup	error in dmaket (error in creation of T)
101*	dsgdc1	lwa < 2*npar
102	dsgdc1	$\mathbf{F}_{2}^{\mathrm{T}}\mathbf{K}\mathbf{F}_{2}$ is not of full rank
103	dsgdc1	failure to converge in <i>dsvdc</i> , this error can usually be cured by increasing the parameter MAXIT in the LINPACK routine <i>dsvdc</i>
201*	dgcvl	dimension error ($nuobs \le 0$ or $ncts \ 1 \le 0$ or $nuobs - ncts \ 1 \le 0$)
202*	dgcvl	error in $ntbl$ ($ntbl < 0$ or $ntbl > ldtbl$)
203*	dgcvl	lwa (length of $work$) < $nuobs - ncts 1 + nobs$
204	dgcvl	lamlim(1) > lamlim(2)
211	dvlop	svals(1) = 0.0d0
212*	dvlop	npsing is incorrect
213	dvlop	lamlim(1) > lamlim(2)
221	dcfcr1	error in dtrco, G is singular
