## Abstract

We begin with a few historical remarks about what might be called the regularization class of statistical model building methods, which include penalized likelihood, support vector machines, robust and quantile nonparametric regression, etc., etc, and the problem of tuning them, spending a little too much time on methods related to Generalized Cross Validation. After that we discuss an approach to variable and pattern selection given very large attribute vectors, based on the LASSO (that is,  $l_1$  penalties) that differs from most approaches to this problem in that it is a mostly global, rather than a sequential, or greedy algorithm, for finding patterns in the data that most influence an outcome.

## Regularization Class of Statistical Models

- $y \in \mathcal{Y}$ : The observations,  $y_1, \dots, y_n$ .
- $x \in \mathcal{X}$ : The attribute vectors,  $x(1), \dots, x(n)$ .
- $f \in \mathcal{H}$ : The model, to be found, relates  $x \in \mathcal{X}$  to  $y \in \mathcal{Y}$ .  $\mathcal{H}$  is the class in which  $f$  is to be found.
- $\mathcal{C}(y, f)$ : Measures goodness of fit of the model to the data.
- $J_\lambda(f)$ : Penalty functional on  $f$ , constrains complexity/degrees of freedom of the model.

The model  $f$  is found as the solution to:  $\min_{f \in \mathcal{H}}$ :

$$\sum_{i=1}^n \mathcal{C}(y_i, f(x(i))) + J_\lambda(f).$$

The (set of) parameter(s)  $\lambda$  controls the tradeoff between fit and complexity, a. k. a bias-variance in some contexts.

One simple example leads to the cubic smoothing spline.

- $y \in R$
- $x \in [0, 1]$
- $f \in W_2^2$  (Sobolev space of functions with square integrable second derivative),
- $\mathcal{C}(y, f) = (y - f(x))^2$
- $J_\lambda(f) = \int_0^1 (f''(x))^2 dx$

On the right: Top:  $\lambda$  too small; Middle  $\lambda$  too big; Bottom  $\lambda$  just right, chosen by Generalized Cross Validation *GCV*. (Golub, Heath and Wahba, 1979, Craven and Wahba, 1979).

## Varieties of Cost Functions (Univariate Case).

	$\mathcal{C}(y, f)$
<b>Regression:</b>	
Gaussian data	$(y - f)^2$
Bernoulli, $f = \log[p/(1 - p)]$	$-yf + \log(1 + e^f)$
Other exponential families	other log likelihoods
Data with outliers	robust functionals
Quantile functionals	$\rho_q(y - f), \rho_q(\tau) = \tau(q - I(\tau \leq 0))$
<b>Classification: <math>y \in \{-1, 1\}</math></b>	
Support vector machines	$(1 - yf)_+, (\tau)_+ = \tau, \tau \geq 0, 0$ otherwise
Other "large margin classifiers"	$e^{-yf}$ and other functions of $yf$
Multivariate (vector-valued $y$ ) versions of the above.	

## Penalty Functionals

---

---

$$J_\lambda(y, f)$$

---

---

### Quadratic (RKHS) Penalties:

$x \in \mathcal{T}$ , some domain, can be very general.

$f \in \mathcal{H}_K$ , a reproducing kernel Hilbert space of functions, characterized by some positive

definite function  $K(s, t)$ ,  $s, t \in \mathcal{T}$ .

$$\lambda \|f\|_{\mathcal{H}_K}^2, \text{ etc.}$$

---

---

### $l_p$ Penalties:

$x \in \mathcal{T}$ , some domain, can be very general.

$f \in \text{span} \{B_r(x), r = 1, \dots, N\}$ ,

a specified set of basis functions on  $\mathcal{T}$ .

$$f(x) = \sum_{r=1}^N c_r B_r(x)$$

$$\lambda \sum_{r=1}^N |c_r|^p$$

---

---

Various combinations of RKHS and  $l_p$  penalties are possible.

$\mathcal{T}$ :

- Anything you can define a positive definite function  $K$  on.
- Anything you can define a set of basis functions  $\{B_r\}$  on.
- Many generalities:  $x = (x_1 : x_2)$ ,  $x_1 \in \mathcal{T}^1, x_2 \in \mathcal{T}^2$ ,  
 $f = f_1 + f_2$   $J_\lambda(f) = J_{\lambda_1}^1(f_1) + J_{\lambda_2}^2(f_2)$ , etc., etc., etc....

## The LASSO-Patternsearch Algorithm:

Data  $\{y_i, x(i)\}, i = 1, \dots, n$

$y_i$  - response of  $i$ th subject with  $p$  attributes:

$$x(i) = (x_1(i), x_2(i), \dots, x_p(i))$$

$y_i, x_1(i), x_2(i), \dots, x_p(i) \in \{0, 1\}^{p+1}$ . (special case and  $p$  large)

Define  $p(x) = \text{Prob}(y = 1|x)$

$f(x) = \log(p(x)/(1 - p(x)))$  [the logit a.k.a log odds ratio].

$$p(x) = e^{f(x)} / (1 + e^{f(x)}).$$

The negative log likelihood  $\mathcal{C}(y, f)$  for  $n$  observations is

$$\mathcal{C}(y, f) = \sum_{i=1}^n -y_i f(x(i)) + b(f(x(i))), \quad b(f) = \log(1 + e^f).$$

The logit  $f(x)$  is modeled as

$$f(x) = \sum_{\ell=0}^N c_\ell B_\ell(x)$$

where the  $B_\ell$  are given basis functions. The  $B_\ell$  depend on  $x = x_1, \dots, x_p$  in some specified way. The  $\{c_\ell\}$  are found by minimizing

$$\mathcal{C}(y, f) + J_\lambda(f)$$

where

$$J_\lambda(f) = \lambda \sum_{\ell=1}^N |c_\ell| \quad l_1 \text{ penalty.}$$

LASSO-Patternsearch involves a **large** to **very large** number  $N$  of basis functions. The  $\ell_1$  penalty  $\sum_{\ell=1}^N |c_\ell|$  has the property that many smaller  $c_\ell$  will be set to 0, depending on  $\lambda$ . For given  $\lambda$ , the  $c_\ell$  can be found numerically in MATLAB for moderate size  $N$ , but that will not be good enough for our purposes. For the LASSO-Patternsearch the basis functions will be all products of the  $x_r$  up to order  $q$ :

$$B_{j_1, j_2, \dots, j_r}(x) = \prod x_{j_1} x_{j_2} \dots x_{j_r}, r = 1, \dots, q.$$

Thus,  $B_{j_1, j_2, \dots, j_r}(x) = 1$  if  $x$  is a  $p$ -vector which has ones in each of the  $j_1, j_2, \dots, j_r$  positions, and  $B_{j_1, \dots, j_r}(x) = 0$  otherwise. The number  $N$  of basis functions is then

$$N = \binom{p}{0} + \binom{p}{1} + \binom{p}{2} + \dots + \binom{p}{q}.$$

For  $q = p$ , (all possible patterns),  $N = 2^p$ .

Note that the conditional distribution of one Bernoulli random variable  $y$  given  $p$  other Bernoulli random variables  $x_1, \dots, x_p$  has  $2^p$  parameters and can be expanded in complete generality in these basis functions. The representation will be most compact, however, if all the risky variables are coded with the risky direction as 1.

A special purpose algorithm which can handle  $N$  up to 4000 on our 3.4 GHz cpu and 4Gb memory workstation is in Shi *et. al.* (The data analysis described later took just 5 seconds.)

## How to choose $\lambda$ ?

We will target the Kullback-Liebler ( $KL$ ) distance between two distributions  $\eta$  and  $\eta_\lambda$  where  $\eta$  is the true distribution and  $\eta_\lambda$  is an estimated distribution:

$$KL(\eta, \eta_\lambda) = E_\eta \log \frac{\eta}{\eta_\lambda}.$$

For example, in the Gaussian case, suppose  $\eta \sim \mathcal{N}(\mu, 1)$  and  $\eta_\lambda \sim \mathcal{N}(\mu_\lambda, 1)$ , then the  $KL$  distance  $KL(\eta, \eta_\lambda) = \frac{1}{2}(\mu - \mu_\lambda)^2$ , leading to minimizing predictive mean square error as the target.

In the Bernoulli case we use the  $GACV$  to choose  $\lambda$ , which targets the  $KL$  distance for members of an exponential family with no nuisance parameters.  $GACV$  is derived starting with the Comparative  $KL$  distance ( $CKL$ ), which ignores that part of  $KL$  distance not depending on  $\lambda$ . The result for Bernoulli data is next.

Notation:  $f(x(i)) \rightarrow f_i$ ;  $f_\lambda(x(i)) \rightarrow f_{i\lambda}$ ;  $p(x(i)) \rightarrow p_i$ ;  
 $p_{i\lambda}(1 - p_{i\lambda}) \rightarrow \sigma_{i\lambda}^2$ .  $H = \{h_{ij}\}$  is inverse Hessian. (like the influence  
matrix in the Gaussian case) with  $i$ th entry  $h_{ii}$ ,  $W = \text{diag}(\sigma_{i\lambda})$ .

$$KL(f, f_\lambda) = \sum_{i=1}^n E_f \log \left[ \frac{\mathcal{L}(f_i)}{\mathcal{L}(f_{i\lambda})} \right]$$

$$CKL(f, f_\lambda) = \sum_{i=1}^n [-p_i f_{i\lambda} + b(f_{i\lambda})]$$

$$CV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda}^{[-i]} + b(f_{i\lambda})]$$

$$ACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \sum_{i=1}^n \left[ \frac{y_i (y_i - \mu_{i\lambda})}{(1 - \sigma_{i\lambda}^2 h_{ii})} \right] h_{ii}$$

$$GACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \text{tr} \mathbf{H} \frac{\sum_{i=1}^n y_i (y_i - \mu_{i\lambda})}{\text{tr} [I - (W^{1/2} H W^{1/2})]}.$$

Notation:  $f(x(i)) \rightarrow f_i$ ;  $f_\lambda(x(i)) \rightarrow f_{i\lambda}$ ;  $p(x(i)) \rightarrow p_i$ ;  
 $p_{i\lambda}(1 - p_{i\lambda}) \rightarrow \sigma_{i\lambda}^2$ .  $W = \text{diag}(\sigma_{i\lambda})$ .  $H = \{h_{ij}\}$  is inverse Hessian,  
 Here  $H = B_*(B'_*WB_*)^{-1}B'_*$ ,  $B_*$  is the  $n \times N_{B0}$  design matrix for  
 the  $N_{B0}$  non-zero  $c_\ell$  in the model.

$$ACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \sum_{i=1}^n \left[ \frac{y_i(y_i - \mu_{i\lambda})}{(1 - \sigma_{i\lambda}^2 h_{ii})} \right] h_{ii}$$

$$GACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \text{tr} H \frac{\sum_{i=1}^n y_i(y_i - \mu_{i\lambda})}{\text{tr}[I - (W^{1/2} H W^{1/2})]}.$$

$$GACV(\lambda) = \sum_{i=1}^n [-y_i f_{\lambda i} + \log(1 + e^{f_{\lambda i}})] + \text{tr} H \frac{\sum_{i=1}^n y_i(y_i - p_{\lambda i})}{n(1 - \frac{1}{n} N_{B0})},$$

The LASSO-Patternsearch has the following steps:

**Step 1.** Minimize  $\mathcal{C}(y, f) + \lambda \sum_{\ell=1}^N |c_\ell|$ , choose  $\lambda$  by *GACV*.

**Step 2.** Enter all basis functions with  $\ell : |c_\ell| > 0$  into a parametric logistic regression model:

$$f(x) = \sum_{\ell: c_\ell > 0} a_\ell B_\ell(x)$$

and fit.

**Step 3.** Select all  $\ell$  for which  $a_\ell$  are significant at the  $q\%$  level, to fit the final model:

$$f(x) = \sum_{\ell: a_\ell \text{ significant}} b_\ell B_\ell(x).$$

$q$  is another tuning parameter, chose  $q$  by *BGACV*. (**What is BGACV?**) Examine patterns ( $B_\ell$ )'s with significant  $b_\ell$ 's.

**Step 4.** Interpret, demonstrate “significance after data mining”.

## What is BGACV?

$$GACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \text{tr} H \frac{\sum_{i=1}^n y_i (y_i - \mu_{i\lambda})}{\text{tr}[I - (W^{1/2} H W^{1/2})]}.$$

$$BGACV(\lambda) = \sum_{i=1}^n [-y_i f_{i\lambda} + b(f_{i\lambda})] + \frac{\log n}{2} \text{tr} H \frac{\sum_{i=1}^n y_i (y_i - \mu_{i\lambda})}{\text{tr}[I - (W^{1/2} H W^{1/2})]}.$$

*GACV* targets *KL* distance. Not the same as selecting the ‘true’ model. *GACV* appears to be conservative in that it almost never misses a ‘true’ pattern (basis function), at the expense of including noise patterns. Similar argument: replace *AIC* with *BIC* by replacing a 2 by  $\log n$  in front of the degrees of freedom. As a heuristic, considering loss of a ‘true’ pattern worse than inclusion of a noise pattern, while trying to have it both ways, a BGACV criteria is employed as a second stage. Interesting theoretical issues here.

Application to progression of myopia from the Beaver Dam Eye Study, BDES 1 to BDES2,  $n = 876$  records of persons aged 60-69 at BDES1. A person whose 'worse eye' scored at a decrease of .75 Diopters or more is labeled  $y = 1$ , and 0 otherwise. About 13% of this group was scored  $y = 1$ .  $p = 7$  predictor variables.

Table 1: Trial Variables and Cutpoints

variable		description	binary cut point (higher risk ) $X = 1$ )
$X_1$	sex	sex	Male
$X_2$	inc	income	< 30
$X_3$	jomyop	juvenile myopia	< 21
$X_4$	catct	cataract	4-5
$X_5$	pky	packyear	>30
$X_6$	asa	aspirin	not taking
$X_7$	vtm	vitamin	not taking

**Step 1.**  $p = 7$  variables,  $q = p = 7$ ,  $N = 2^7$  basis functions,  
minimize  $\mathcal{C}(y, f) + \lambda \sum_{\ell=1}^{128} |c_{\ell}|$ , choose  $\lambda$  by GACV.  
Twelve patterns survived Step 1.

**Step2.** Parametric logistic regression for patterns surviving Step 1:  
Enter the patterns surviving Step 1 into a parametric logistic regression model:

The result for the 12 patterns is above: Confidence intervals depicted reflect **Step 3**

**Step 3.** Select all  $\ell$  for which  $a_\ell$  are significant at the  $q\% = 96.92\%$  ( $BGACV$ ) level, to fit the final model. The patterns passing this test are:

1. Constant
2. **catct** (Cataract)
8. **pky vtm** (Packyear  $> 30$  and not taking vitamins)
12. **sex inc jomyop asa** (Male, low income, juvenile myopia, not taking aspirin)
13. **sex inc catct asa** (Male, low income, cataract, not taking aspirin)

Step 3.(continued) Fit the final model with the five patterns significant at the 96.92% (BGACV) level.

$$f(x) = \sum_{\ell: a_\ell \text{ significant}} b_\ell B_\ell(x).$$

The (refitted) model is

$$\begin{aligned} & f(\text{catct}, \text{pky}, \text{vtm}, \text{sex}, \text{inc}, \text{jomyop}, \text{asa}) \\ & - 3.29 + 2.42 * \text{cact} + 1.18 * \text{pky} * \text{vtm} \\ & + 1.84 * \text{sex} * \text{inc} * \text{jomyop} * \text{asa} + 1.08 * \text{sex} * \text{inc} * \text{cat} * \text{asa}. \end{aligned}$$

Step 4. Having done some "data mining", the investigators can go back and look at classes of people who may not have been examined separately before. For example:

catct	pky	not take vitamins	risk of progression
1	1	1	$17/23 = 0.7391$
1	1	0	$7/14 = 0.5000$
0	1	1	$22/137 = 0.1606$
0	1	0	$2/49 = 0.0408$
1	0	1	$18/51 = 0.3529$
1	0	0	$19/36 = 0.5278$
0	0	1	$22/363 = 0.0606$
0	0	0	$13/203 = 0.0640$

Looking at the smokers: (1, 1, 1, 1):

Looking at the smokers: smokers with cataract are relatively protected by taking vitamins, and smokers without cataract are also relatively protected by taking vitamins. For non smokers taking or not taking vitamins makes no (significant) difference.

Physiologically meaningful - recent literature suggests:

- a) Certain vitamins are good for eye health.
- b) Smoking depletes the serum and tissue vitamin level, especially Vitamin C and Vitamin E.

(Although as usual, a “randomized controlled clinical trial would provide the best evidence of any effect of vitamins on progression of myopia in smokers”)

To check on the “significance” of the patterns, randomly scramble the  $y$ s while keeping the  $x$ 's fixed, and apply the entire LASSO-Patternsearch algorithm to see how often false patterns are generated. Repeat 600 times. (Statistical theory is not clear on properties of multistep procedures)

Detection of noise patterns found in scrambled data compared to observed  $p$  values:

Log  $p$  values of the patterns found (out of 600) are plotted (l. to r. top to bottom) for observed patterns of size 1,2,3,4. Red lines are for the observed  $p$ -values for *catct*, *pky vtm*, none, and *sex inc jomyop asa* (lower) and *sex inc catct asa* (upper).

Figure 1: Upper red line suggests that *sex inc catct asa* is borderline significant.

Genetic Data (realistic simulation, not ours, not released yet)

$y$  = phenotype,  $x$  = SNPs, alleles, covariates, after coding as 1 or 0, 9192 variables.

Train: 1500 cases, 2000 controls

Tune: 1500 cases, 2000 controls

Test: 1500 cases, 2000 controls.

Pre-screen step: 9192 variables reduced to  $N = 2559$  basis functions for the LASSO step. Final model has 8 main effects and 3 interactions. Using  $p = .5$  as a classifier, a competitive 12.6% error rate was obtained. Identified a SNP near most of the genes that were used to generate the data.
